17   **Running title:** Primers for quantitative metabarcoding

18

19    **Abstract**

20    DNA metabarcoding is a technique used to survey biodiversity in many ecological settings, but  
21    there are doubts about whether it can provide quantitative results, *i.e.* the proportions of each  
22    species in the mixture as opposed to a species list. While there are several experimental  
23    studies that report quantitative metabarcoding results, there are a similar number that fail to  
24    do so. Here we provide the rationale to understand under what circumstances the technique  
25    can be quantitative.

26    Basically, we simulate a mixture of DNA of  $S$  species with a defined initial abundance  
27    distribution. In the simulated PCR, each species increases its concentration following a certain  
28    amplification efficiency. The final DNA concentration will reflect the initial one when the  
29    efficiency is similar for all species; otherwise, the initial and final DNA concentrations would be  
30    poorly related. Although there are many known factors that modulate amplification efficiency,  
31    we focused on the number of primer-template mismatches, arguably the most important one.  
32    We used 15 common primers pairs targeting the mitochondrial COI region and the  
33    mitogenomes of ca. 1200 insect species.

34    The results showed that some primers pairs produced quantitative results under most  
35    circumstances, whereas some other primers failed to do so. Many species, and a high diversity  
36    within the mixture, helped the metabarcoding to be quantitative. In conclusion, depending on  
37    the primer pair used in the PCR amplification and on the characteristics of the mixture analysed  
38    (*i.e.*, high species richness, low evenness), DNA metabarcoding can provide a quantitative  
39    estimate of the relative abundances of different species.

40

41    **Introduction**

42    Ideally, metabarcoding should be a technique used to quantify species abundance in natural  
43    communities ( $C_i$  in Figure 1) using high-throughput DNA sequencing (HTS). This is normally

44 accomplished by sampling the organisms in the community using a particular sampling method  
45 ( $S_i$ ; Morinière et al., 2016) or by collecting fragments of DNA shed from organisms  
46 (environmental DNA or eDNA,  $E_i$ ; Taberlet, Coissac, Hajibabaei, & Rieseberg, 2012). The  
47 target can also be the subset of the community consumed by a predator or an herbivore in  
48 what is termed diet analysis ( $D_i$ ; Pompanon et al., 2012); the diet is estimated from the DNA  
49 remains in faecal samples or in the gut contents of the consumer ( $G_i$ ). In all cases, the DNA is  
50 extracted into a solution with DNA of many species at relative abundances  $O_i$ . Then, the  
51 extracted DNA can be directly sequenced (shotgun metagenomics) or sequenced following  
52 amplification via PCR of one or more genomic regions (amplicon metabarcoding). Finally, the  
53 obtained DNA reads  $R_i$  are assigned to species or OTUs ( $F_i$ ). Every process described in  
54 Figure 1 introduces its own biases (Leray & Knowlton, 2017; Pompanon et al., 2012), and so  
55 the estimation of the community composition  $C_i$  (or  $D_i$  in diet analysis) from the final read  
56 abundance ( $F_i$ ) is a daunting task that we are now just beginning to grasp (Barnes & Turner,  
57 2016; Elbrecht, Vamos, Meissner, Aroviita, & Leese, 2017). Only when all biases are avoided  
58 or corrected, will it be possible to perform quantitative metabarcoding.

59 The processes involved in the transformation of species counts or biomass ( $C_i$  or  $D_i$ ) to the  
60 DNA solution ( $O_i$ ) are complex. For instance, in the diet analysis, not all the DNA of the  
61 consumed species (or even of different tissues of the same species) is digested with the same  
62 efficiency. The case of environmental DNA is even worse, as there are many factors that affect  
63 the production and stability of eDNA (origin, state, decay, transport, persistence; Barnes &  
64 Turner, 2016). The extraction of DNA from samples ( $G_i$ ,  $E_i$  or  $S_i$ ) to the solution ( $O_i$ ) would  
65 apparently be straightforward, but this is far from true for some organisms: Ponon et al. (2016)  
66 report a difference of *ca* 300 times in the extracted DNA yield (before amplification) from the  
67 same number of pollen grains of three plant species. These authors attribute this variability to  
68 interspecific differences in pollen wall structure, pollen size, genome size, the number of  
69 marker copies and DNA extraction efficiency.

70 The processes leading from the extracted DNA ( $O_i$ ) to the relative species abundance ( $R_i$ ) are  
71 no better. Amplicon metabarcoding (shaded region in Figure 1) is mostly affected by the PCR  
72 amplification step using ‘universal’ primers targeting a certain region of the genome. Universal  
73 primers do not perfectly match the DNA of all species, and so there is a variable number of  
74 template-primer mismatches across species. Consequently, some species are better amplified  
75 than others and the proportions in the final mixture do not reflect the original proportion of each  
76 species (Elbrecht and Leese, 2015; Leray et al., 2013; Bista et al., 2018). There are other  
77 complications in the PCR step that produce more biases; for instance, the use of indexed PCR  
78 primers (used to minimize the per sample cost of sequencing by allowing the sequencing of  
79 many samples in a single run) might induce further biases (Leray & Knowlton, 2017; O’Donnell,  
80 Kelly, Lowell, & Port, 2016). The avoidance of the PCR step (shotgun metagenomics) would  
81 in theory render a faithful list of  $R_i$  (Bista et al., 2018), and this is what is mostly used in microbial  
82 metabarcoding nowadays (Jovel et al., 2016). However, in eukaryotes, the scarcity of  
83 assembled genomes and the vast amount of sequencing depth needed, makes shotgun  
84 metabarcoding still unsuitable in most circumstances (Gómez-Rodríguez, Crampton-Platt,  
85 Timmermans, Baselga, & Vogler, 2015; Zhou et al., 2013).

86 Whether the metabarcoding provides quantitative results has been usually evaluated using  
87 mock communities of known composition that are amplified and sequenced, or using a  
88 classical quantification method alongside the DNA metabarcoding. There is a growing number  
89 of these studies and the results are contradictory (Table 1). Whilst many studies report a  
90 significant quantification, albeit with a variable explanatory power, many others do not.  
91 According to these results, the right question to ask is not whether, but in which circumstances,  
92 is DNA metabarcoding quantitative.

93 Here we do not attempt to tackle all the problems in quantitative metabarcoding depicted in  
94 Figure 1, but just a subset of them. We concentrate on the template-primer bias that  
95 complicates the quantification of the initial DNA concentration in a heterogeneous solution ( $O_i$ )

96 from the reads obtained after PCR amplification and HTS sequencing ( $R_i$ ). We focus on this  
97 for two reasons. First, the process  $O_i \rightarrow R_i$  is an obligatory step for diet ( $G_i$ ), eDNA ( $E_i$ ), and  
98 fresh or well conserved sample analyses ( $S_i$ ), and so our contribution can potentially benefit  
99 people in several fields. Second, whereas there are several causes that influence the number  
100 of reads  $R_i$  (i.e. genome size, mitochondrial copy number, ...), the number of template-primer  
101 mismatches is probably the most important one (Elbrecht & Leese, 2015; Mao, Zhou, Chen, &  
102 Quan, 2012; Pinto & Raskin, 2012; Piñol, Mir, Gomez-Polo, & Agustí, 2015). We address the  
103 problem using a simple model that simulates the process of PCR amplification in  
104 heterogeneous mixtures. We test the model using the mitogenomes of ca. 1200 species of  
105 insects available in RefSeq and 15 primer pairs targeting the COI region (Elbrecht & Leese,  
106 2017a). Maybe the COI region is not the best suited for designing metabarcoding primers  
107 (Deagle, Jarman, Coissac, Pompanon, & Taberlet, 2014; Elbrecht et al., 2016), but it remains  
108 the region with most extensive information in genomic databases. The objectives are to  
109 evaluate *in silico* which primer pairs and which characteristics of species mixtures provide a  
110 quantitative relationship between the pre- and post-PCR marker abundance of the species in  
111 the mixture.

112

## 113 **Material and Methods**

### 114 Rationale of the model

115 Let's consider a mixture of DNA of  $S$  species each with original DNA concentration  $O_i$  that is  
116 PCR-amplified with a universal primer pair. Each species increases its concentration to  $F_i$   
117 according to a certain efficiency  $\Lambda_i$  (here we are assuming that  $R_i$  in Figure 1 equals  $F_i$ , and so  
118 the biases in the bioinformatic pipeline from read number to species abundance are assumed  
119 to be negligible in the present application),

120 
$$F_i = \Lambda_i \cdot O_i \quad \text{Eq. 1}$$

121  $\Lambda_i$  varies between 1 (no amplification) and  $2^c$  (maximum amplification, with  $c$  the number of  
122 PCR cycles).  $F_i$  will be proportional to  $O_i$  when  $\Lambda_i$  is the same for all species; on the other hand,  
123 when  $\Lambda_i$  is very different among species,  $F_i$  would poorly reflect  $O_i$ . This model is equivalent to  
124 the basic one of Suzuki and Giovannoni (1996).

125 In DNA metabarcoding, only the relative proportions of each species in the mixture are of  
126 interest. Let's call  $o_i$  and  $f_i$  the original and final relative concentration of DNA of species  $i$  in  
127 the mixture. These two magnitudes are related by an equation like the previous one

128 
$$f_i = \lambda_i \cdot o_i / a \quad \text{Eq. 2}$$

129 where  $a = \sum_{i=1}^S \lambda_i \cdot o_i$  is a scaling constant to assure that  $1 = \sum_{i=1}^S f_i$ . Here  $\lambda_i$  is the relative  
130 amplification efficiency of species  $i$  and belongs to the interval  $(0, 1]$ .

131 The application of the model is straightforward. First, it requires a pool of species and the  
132 primer pairs of interest. Second, a method to generate random mixtures of species with a  
133 certain initial abundance distribution ( $o_i$ ). Third, an estimation of the amplification efficiency  $\lambda_i$   
134 of each species in the mixture. Finally, the computation of  $f_i$  using equation 2. Figure 2  
135 summarizes the computational pipeline that implements the model above. On its left-hand side,  
136 there are the procedures that calculate the template-primer mismatches for each combination  
137 of the species and primer pairs in the pool. In the right-hand side, there is the algorithm that  
138 performs many simulations for each primer pair and compares  $o_i$  with  $f_i$ .

139 Primer pairs and species

140 We only considered the 15 COI primer pairs targeting the mitochondrial Folmer region (Folmer,  
141 Black, Hoeh, Lutz, & Vrijenhoek, 1994) analysed by Elbrecht and Leese (2017a) (Tables 2 and  
142 3). The selection includes the most common universal primer pairs currently used for DNA  
143 metabarcoding of insects. We compiled a pool  $P$  of 1204 species of insects with an assembled

144 mitochondrial genome at RefSeq (<ftp://ftp.ncbi.nlm.nih.gov/refseq/release/mitochondrion/>  
145 visited at 25-May-2017) (see the distribution of the species among orders in Figure S1).

146 We calculated the number of primer-template mismatches for each primer and each  
147 mitochondrial genome using the function `matchPattern` of the R package `Biostrings` (Pagès,  
148 Aboyoun, Gentleman, & DebRoy, 2017). We limited the maximum number of mismatches per  
149 primer to five. When the primer mapped in more than one region, we choose the region with  
150 the lowest number of mismatches.

151 Next, we combined the pairs of primers in table 3 and computed the total number of primer-  
152 mismatches in the two primers and the amplicon length. We only retained the primer  
153 pair/genome combinations that produced an amplicon of length equal to the expected amplicon  
154 length for each primer pair (table 3). As primer pair #15 produced a very low number of useful  
155 species to analyse (table 3), it was not considered further here.

156 Generation of random communities

157 A subset of  $S$  species was randomly sampled from the pool of species  $P$ . The relative  
158 proportions of each species in the mixture was established following a geometric model  
159 (Magurran, 2004)

160 
$$o_i = C_k \cdot k \cdot (1 - k)^{i-1} \quad \text{Eq. 3}$$

161 Where  $o_i$  is the proportion of the species  $i$  in the mixture,  $k$  is the parameter of the model and  
162  $C_k = [1 - (1 - k)^S]^{-1}$  is a constant that makes  $\sum_{i=1}^S o_i = 1$ . The parameter  $k$  belongs to the  
163 interval  $(0, 1)$ . Small values of  $k$  produce communities in which the species have similar  
164 abundances, whereas high values of  $k$  produce communities dominated by a few abundant  
165 species.

166 Estimation of the PCR amplification efficiency

167 It is acknowledged that the number of template-primer mismatches influences the efficiency of  
168 the PCR reaction. However, much less is known about the nature of the relationship between  
169 number of mismatches vs. efficiency. Here we use a basic model in which each new mismatch  
170 reduces the efficiency in a certain proportion  $\beta$ :

171  $\lambda_i = \beta^{-m_i}$  Eq. 4

172 Where  $m$  is the total number of primer-template mismatches in both the forward and the  
173 reverse primers. According to this model, the number of mismatches has a multiplicative effect  
174 on the amplification efficiency, and so when  $m_i = 0$ ,  $\lambda_i = 1$  (perfect match and maximum  
175 amplification efficiency); when  $m_i = 1$ ,  $\lambda_i = 1/\beta$ ; when  $m_i = 2$ ,  $\lambda_i = 1/\beta^2$ ; and so on.

176 In this application, we used two different formulations of the model above. In the first one  
177 (model 1),  $m$  is the number of template-primer mismatches in the entire length of both the  
178 forward and reverse primers; in the second one (model 2),  $m$  is the number of template-primer  
179 mismatches that occur only in the five 3'-end positions of both the forward and reverse primers.  
180 We have done so because mismatches closer to the 3' end of the primer has a greater effect  
181 on the PCR efficiency than mismatches occurring further away from the 3' end of the primer  
182 (Stadhouders et al., 2010).

183 Parameters of the simulation

184 For this model to be useful, the parameters of the model  $S$ ,  $k$ , and  $\beta$  must have realistic values,  
185 i.e. they should correspond to values normally found in natural communities that could  
186 eventually be subjected to DNA metabarcoding. The number of species in a sample can be  
187 very different depending on the studied community. Here we are pretending to simulate  
188 communities of insects in temperate areas, and so a reasonable range for  $S$  in samples of  
189 temperate communities would be 5-100.

190 To find reasonable values of  $k$ , we took advantage of a dataset of insects in tree canopies of  
191 a citrus grove (Piñol, Espadaler, & Cañellas, 2012). We used biomass data of species of  
192 Dermaptera, Coleoptera, Hemiptera, Neuroptera, Psocoptera, and Hymenoptera from 133  
193 sampling events with 5 or more species. Then we fitted a geometric model (equation 3) to the  
194 species biomass for every sampling event. The fitted  $k$  values varied between 0.2 and 0.95  
195 (Figure S2a). The goodness of fit of the geometric model to the data was very high (Figure  
196 S2b), indicating that the use of a geometric model to describe the relative proportions of the  
197 species is sound.

198 The  $\beta$  value that relates the number of template-primer mismatches to the amplification  
199 efficiency was estimated from Piñol et al. (2015), who report a significant negative relationship  
200 between the logarithm of the amplification efficiency and the number of template-primer  
201 mismatches:

202 
$$\log_{10}y = -0.25 + 0.61 \cdot (-m_T), r^2 = 0.73, F_{1,9} = 24.35, P = 0.0008$$

203 
$$\log_{10}y = -1.09 + 1.73 \cdot (-m_5), r^2 = 0.81, F_{1,9} = 38.24, P = 0.0002$$

204 where  $m_T$  is the total number of template-primer mismatches in the entire length of the both  
205 primers, and  $m_5$  is the total number of mismatches in the five 3'-end nucleotides of the forward  
206 and reverse primers. We are not aware of any other study that explicitly states the relationship  
207 between the number of template-primer mismatches and the amplification efficiency.

208 The above empirical relationships are equivalent to equation 4, where  $\beta$  can be estimated as  
209  $10^{\text{slope}}$ . Thus, for model 1,  $\beta = 10^{0.61} = 4.07$  and for model 2,  $\beta = 10^{1.73} = 53.70$ . The error in the  
210 estimated values of the slope translates to the estimate of  $\beta$ : the 95% interval of confidence  
211 for  $\beta$  in model 1 is (2.1 to 7.8) and for model 2 is (12.6 to 234).

212 Simulations

213 For each primer pair considered, we ran 10000 simulations using an R script that performed  
214 the following steps (summarized in Figure 2):

- 215 1. We generated a random number of species  $S$  in the community between 5 and 100.  
216 (The random number and all those below followed a uniform distribution).
- 217 2. We randomly chose  $S$  species from the pool  $P$  of species.
- 218 3. We generated a random value of  $k$  between 0.2 and 0.95.
- 219 4. We used this  $k$  value to estimate the initial relative DNA concentration  $o_i$  of each of the  
220  $S$  species in the community using equation 3.
- 221 5. We generated a random value of  $\beta$  in the interval (2, 8) for model 1 and in the interval  
222 (12, 240) for model 2.
- 223 6. Using equation 4, we calculated the relative amplification efficiency  $\lambda_i$  of each species  
224 in the community using the above  $\beta$  value and the previously calculated number of  
225 mismatches between this primer pair and each species. For model 1 we used the  
226 number of template-primer mismatches in the entire length of the primers; for model 2  
227 we used only the mismatches occurring in the five 3'-end positions of both primers.
- 228 7. Finally, we calculated the relative DNA concentration of each species in the mixture  $f_i$   
229 from Equation 2 using the above estimates of  $\lambda_i$  and  $o_i$ .
- 230 8. Each simulation was summarized by the linear correlation coefficient  $r_i$  between  $f_i$  and  
231  $o_i$ . We also calculated whether the most abundant species at the beginning ( $o_i$ ) was  
232 also the most abundant at the end of the PCR reaction ( $f_i$ ).

233

234 Analysis of the results of the simulations

235 For each primer pair, we set the following statistical test:

- 236  $H_0: r = 0$  (there is not a linear relationship between  $o_i$  and  $f_i$ )  
237  $H_1: r \neq 0$  (there is a linear relationship between  $o_i$  and  $f_i$ )

238 To decide between  $H_0$  and  $H_1$  we considered the empirical 95% confidence interval (CI) of the  
239  $r_i$  distribution: when  $0 \in CI$  we accepted  $H_0$  and when  $0 \notin CI$  we accepted  $H_1$ . The probability  
240 of error when accepting  $H_1$  is 0.05.

241 For each set of simulations of each primer pair we also calculated the proportion in which the  
242 same species was the most abundant before and after the simulated PCR reaction. If this value  
243 was above 0.95, then it would be safe to consider that the observed most abundant species  
244 was correctly guessed with a probability of 0.95.

245 Finally, with all the simulations of all the primer pairs we calculated using a linear model the  
246 proportion of the variance of  $r$  (after the Fisher z-transformation) associated with the factors:  
247 primer pair;  $S$ ;  $k$ ;  $\beta$ ; and all 2-way interactions.

248 All the calculations were conducted with R in-house scripts (R Core Team, 2016) also using  
249 the database manager SQLite (Müller, Wickham, James, & Falcon, 2017).

250

## 251 **Results**

### 252 Number of mismatches

253 Considering the entire length of both the forward and the reverse primers, the median of the  
254 number of template-primer mismatches was 0 for primer pairs #10 to #14, 1 for primer pair #7,  
255 and 3 or higher for the rest of primer pairs (Figure 3A). When only the five 3'-end positions of  
256 each primer were considered, the median of the number of template-primer mismatches was  
257 2 for primer pair #4, 1 for primer pairs #2 and #5, and 0 for the remainder (Figure 3B). Primer  
258 pairs #10 and #14 were especially good, as more than 99% of the tested species (~1150) had  
259 no template-primer mismatches in the five 3'-terminal positions.

### 260 Relationship $o_f$

261 Considering the entire length of both the forward and the reverse primers, the simulations of  
262 primer pairs #1, #2, #3, and #5 generated an empirical 95% confidence interval (CI) for the  
263 linear correlation coefficient that included the 0 value, indicating that it is not justified to assume  
264 a significant linear relationship between  $o_i$  and  $f_i$  (Figure 4A). The opposite was true for the rest  
265 of primer pairs. The relationship  $o_i-f_i$  was especially good for primers pairs #10 to #14, and to  
266 a lesser extent to primer pair #7; for all these primer pairs, it is safe to assume that the final  
267 concentration of DNA after the PCR reaction ( $f_i$ ) quantitatively reflects what was there initially  
268 ( $o_i$ ). However, for none of the primer pairs analysed it is safe to assume that the most abundant  
269 species after the PCR reaction was the most abundant initially (Table 4).

270 The overall picture was slightly better when only the five 3'-terminal bases of both primers were  
271 considered (Model 2). In this case, only primer pairs #4 and #5 generated a CI for  $r$  that  
272 included the 0 value, while the opposite was true for the rest of them (Figure 4B). Primer pairs  
273 #10, #11, #12, and #14 where again especially good, generating CI that were always above  
274 the value of  $r=0.9$ . In addition, for primers pairs #10 to #14, it is safe to assume that the most  
275 abundant species was correctly attributed (Table 4).

276 Effect of the characteristics of the mixture of species on the correlation  $o_i-f_i$

277 The mixture of the species is characterised in the model by  $S$  and  $k$ . When the number of  
278 species  $S$  in the random sample was low (5-15) the relationship  $o_i-f_i$  was not significant for all  
279 the primers pairs except #10 to #14 (Model 1; Figure S3-A) and for #10 to #14, #3, #6 and #8  
280 (Model 2; Figure S3-B). When  $S$  was high (51-100) all primer pairs produced a significant linear  
281 correlation between  $o_i-f_i$  for both models (Figure S3-CD).

282 Low values of the parameter  $k$  of the geometric distribution (i.e., species with not very different  
283 abundances;  $k < 0.45$ ) produced worst results, especially for Model 1, that when  $k$  was higher  
284 ( $k > 0.70$ ), where only primer pair #5 (Model 1) and #4 and #5 (Model 2) had a 95% CI that  
285 included the 0 value (Figure S4).

286 Relative importance of each factor on the magnitude of the correlation  $o_i-f_i$

287 We decomposed the variance of the correlation coefficient  $r$  in the 140 000 runs (14 primers  
288 pairs x 10000 runs each) according to the factors considered in Model 1 and 2 (Table 5). For  
289 both models 1 and 2, the main factor was the choice of primer pair that accounts for more 20%  
290 of the total variance;  $k$  (models 1 and 2) and  $\beta$  (model 1) also had some importance in the  
291 decomposition, but not  $S$ . However, in both models most of the variance was unexplained by  
292 the considered factors. This implies that there are more important reasons on top of those  
293 considered above that affect the correlation coefficient  $r$ . In the model, the main reason is the  
294 idiosyncratic species composition of each simulated mixture; this means that two simulations  
295 with identical  $S$ ,  $k$  and  $\beta$  values, but with a different choice of species will likely produce a very  
296 different value of  $r$ .

297 The primer pairs that do better (Figure 4) are those with fewer template-primer mismatches  
298 (Figure 5-AB). Indeed, the mean number of mismatches per primer is linearly correlated with  
299 the mean  $r$  of the simulations for both models. However, and following the rationale of the  
300 model, the mean  $r$  was even better correlated with the standard deviation of the number of  
301 mismatches per primer (Figure 5-CD). Consequently, a proxy for the potential of a certain  
302 primer pair for conducting quantitative metabarcoding would be the mean, or even better, the  
303 standard deviation, of the template-primer mismatches of that primer within the pool of the  
304 genomes of interest.

305

## 306 **Discussion**

307 The model is intended to establish whether the results of a part of the metabarcoding analysis,  
308 but not of the entire metabarcoding pipeline (Figure 1), are *likely* to be quantitative. By  
309 quantitative we more precisely mean that there exists a significant linear correlation (at a  
310 certain significance level) between the relative DNA concentration before and after the PCR

reaction ( $O_i$  and  $F_i$  in Figure 1) using a particular primer set and a group of organisms. What the model does not provide is the *certainty* of a significant relationship for a given analysis. This approach may have greater utility for the analysis of eDNA samples or community DNA than for gut content analyses, given the additional sources of error associated with digestion. Also, the number of different species in the mix is likely to be much lower in predator/herbivore gut samples than in eDNA samples.

It is also important to realize that the model only considers one of the many factors that affect the PCR amplification efficiency, i.e. the number of template-primer mismatches. Among the non-considered factors there are variable mtDNA copy number, the genome size, the position and type of the mismatches (Stadhouders et al., 2010), and the G+C content of the amplicon (Wintzingerode, Göbel, & Stackebrandt, 1997). However, we are aware of only one study that explicitly correlated the number of mismatches with the amplification efficiency. In that study, the variance explained by the number of mismatches was ~0.75 of the total (Piñol et al., 2015), so there is only a mere ~0.25 of the total variance in the amplification efficiency left to be explained by the rest of the unaccounted factors mentioned above. Thus, this model makes the strong assumption that the PCR amplification efficiency mainly depends on the number of template-primer mismatches, and considering the empirical information available so far, it is a reasonable assumption.

When summarizing which factors most affect the correlation between the pre- and post-PCR DNA concentrations ( $o_i-f_i$ ) it stands out that the most important of them all was not included in the model (i.e., the unexplained variance in Table 5). This unexplained variance is the idiosyncratic species composition of the mixture and their relative abundances. The following example shows that there can be huge effects even when all the model parameters are the same. In the mixture of table 6a ( $S = 10$ ,  $k = 0.4$ ,  $\beta = 4$ ) the linear correlation  $o_i-f_i$  is highly significant ( $r = 0.996$ ,  $P < 0.001$ ). In the mixture in table 6b, the species (and the parameters of the model) are the same as in 6a, but now the most abundant species is #8 instead of #1;

337 in this case the relationship  $o_i-f_i$  becomes non-significant ( $r = 0.46$ ,  $P > 0.05$ ). This example  
338 shows that it is impossible to be sure that a particular metabarcoding analysis will produce a  
339 significant  $o_i-f_i$  correlation, unless we know in advance the exact composition of the species in  
340 the mixture. For this reason, we highlighted above that our analysis can only provide the  
341 *likelihood* of the PCR step of a certain metabarcoding experiment being quantitative, but never  
342 its *certainty*.

343 Table 5 also shows that the factors considered in the model are also important. Below we  
344 discuss the importance of the selected primer sets and the macroscopic characteristics of the  
345 mixture, i.e. the species richness  $S$  and the slope ( $k$ ) of their relative abundances.

346 Choice of primer pairs

347 The choice of primer pairs is the most important decision to make for DNA metabarcoding. The  
348 model suggests that some of the primers tested in this study are better suited than others for  
349 quantitative DNA metabarcoding. Among the primer pairs tested here, the best choice seems  
350 to be the primer pair #10 (Gibson et al., 2014) and the primer pairs #11 to #14 (Elbrecht &  
351 Leese, 2017a). All of them guarantee (with a probability of 0.95) a significant linear relationship  
352  $o_i-f_i$ ; moreover, the linear correlation coefficient between pre- and post-PCR DNA  
353 concentrations is likely to be high (in the range 0.4 – 1) (Figure 4). The rest of the primer pairs,  
354 except #4 and #5, also provide significant results, but with lower  $r$  values. Primers sets #10 to  
355 #14 are highly degenerated, so, it is justified that they amplify better *in silico* than other sets  
356 with a much lower degeneracy (e.g., #4 and #5).

357 The primer pair #10 (Gibson et al., 2014) was developed to amplify a 310 bp region of many  
358 families of arthropods. This primer contains the universal base inosine (I); in our calculations,  
359 we considered that inosine could pair any base, but, in reality, its capacity to pair with the four  
360 bases is variable (Martin, Castro, Aboul-ela, & Tinoco, 1985); besides, the use of inosine  
361 increases the price of the primers. The four primer pairs of Elbrecht and Leese (2017a) are all

362 possible combinations of two forward and two reverse primers that produce amplicons of  
363 different length. As these primers pairs were developed recently, they have been hardly used  
364 by other researchers for DNA metabarcoding (Krehenwinkel et al., 2017); considering our  
365 results, we would recommend their use. In any case, *in vivo* validations of primers sets with  
366 mock samples of the species of interest is still advisable before embarking on a metabarcoding  
367 study.

368 The above recommendation does not imply that the rest of the primers are of no use in  
369 metabarcoding. Some of them can have great coverage of some groups, like primers #5 that  
370 are particularly good for Lepidoptera (Zeale, Butlin, Barker, Lees, & Jones, 2011) and have  
371 been used with profit for the characterisation of the diet of bats (Clare, Symondson, & Fenton,  
372 2014).

373 Characteristics of the mixture of species

374 The number of species in the mixture and their relative abundance were also important in the  
375 quantification of the species. The number of species  $S$  does not explain the magnitude of  $r$   
376 (Table 5) but affect the width of the CI of  $r$  (Figure S3). When  $S$  is low, most primer pairs (#1  
377 to #9) give a CI of  $r$  that includes the value  $r=0$ ; on the contrary, when  $S$  is high all tested primer  
378 pairs guarantee (at the 95% level) a quantitative metabarcoding. This result is a consequence  
379 of the higher effect that an outlier (e.g., one species with one or more mismatches, but very  
380 abundant initially, in an assemblage where most species have no mismatches) has on  $r$  when  
381  $S$  is low than when  $S$  is high. Thus, as a rule, the higher the number of species in the mixture,  
382 the higher the likelihood of the results reflecting the original relative abundance of the species.  
383 These results have a relevant corollary for diet analysis: DNA metabarcoding is more likely to  
384 provide a quantitative diet for polyphagous than for stenophagous predators. This implies that  
385 it would be more quantitative when analysing polyphagous species in diverse tropical  
386 ecosystems than in less diverse temperate ecosystems. Thus, good dietary quantification  
387 would be expected, for example, for larger predators eating many small prey (e.g. an

388 insectivorous bird or bat) than for a small predator (e.g. an insect) that may be polyphagous  
389 but have few prey in its guts at any moment in time.

390 The relative abundance of the species in the mixture also affects the quantification of species  
391 by metabarcoding. When the relative abundance of the species is similar among them ( $k$  low)  
392 the method was less reliable than when a few species were very abundant and the rest were  
393 not ( $k$  high) (Figure S4). This behaviour is easy to understand by observing equation 2 that  
394 describes the PCR reaction. The linear correlation  $\rho_{-f_i}$  is going to be higher when the variance  
395 of  $\rho_i$  (in relation to  $\lambda_i$ ) is also high.

396 Relationship between the number of mismatches and amplification efficiency

397 Here we considered that all mismatches have the same importance and that each new  
398 mismatch reduces the amplification efficiency in the same factor  $\beta$  (equation 4). However, there  
399 are other characteristics of the mismatches, besides their total number, that affect the  
400 amplification efficiency.

401 It is known that mismatches near the 3'-end of the primer have a higher effect than in other  
402 positions of the primer (Bru, Martin-Laurent, & Philippot, 2008; Stadhouders et al., 2010). We  
403 partially took into account this effect by using two versions of the model, one considering all  
404 mismatches in both primers (model 1) and one considering only the mismatches in the five 3'-  
405 terminal positions of both primers (model 2). The results produced similar conclusions with  
406 both versions of the model regarding which primers produced better quantitative results.

407 It is also known that some types of mismatch reduce more than others the amplification  
408 efficiency (Kwok et al., 1990; Stadhouders et al., 2010; Wright et al., 2014). In general, it has  
409 been reported a general purine-purine > pyrimidine-pyrimidine > purine-pyrimidine hierarchy  
410 of mismatch impact (Stadhouders et al., 2010), but there are some discrepancies. In addition,  
411 most of the studies refer only to the 4-5 bases in the 3'-end of the primers, and very little is  
412 known about mismatches in the rest of the primer positions (Sipos et al., 2007).

413 Considering that there is not enough quantitative information about the effect of the mismatch  
414 position and type throughout the entire length of the primer, we preferred to keep the model  
415 simple. More experimental work in this respect would be needed to parametrise with  
416 confidence more realistic models of amplification efficiency. It is worth mentioning that other  
417 models already consider the position, adjacency and type of the mismatches (Elbrecht &  
418 Leese, 2017b), but their parametrisation is limited as it is based on the scarce empirical  
419 information available.

420 If proved robust, the assumption that the amplification efficiency depends basically on the  
421 number of template-mismatches suggests a possible avenue for quantifying mixtures amplified  
422 with any primer set. Once (or when) the species composition of the mixture is known, and  
423 given the number of primer-template mismatches, it would be possible to estimate the initial  
424 abundance of each species ( $o_i$ ) using equation 2 in reverse. Thus, it should be possible, at  
425 least in theory, to quantify the relative composition of any mixture in two steps: the first one  
426 would provide the list of species and the second one the relative abundance of each one.

427 Limitations of the model

428 The model was applied to approximately 1200 species of insects with a sequenced  
429 mitogenome in RefSeq. The model says nothing about other genomic regions, groups of  
430 organisms, or sets of primers. For instance, it could be perfectly possible that some of the  
431 primers that did not perform well in our analysis, behave much better for a subset of insect  
432 orders. However, it is fair to suppose that the same kind of conclusion would be obtained  
433 elsewhere: some primer pairs would do better than others, mixtures with more species would  
434 do better than mixtures with fewer species, and mixtures with less evenness would also do  
435 better than mixtures with a higher evenness. So, it would be worthwhile to conduct similar  
436 studies to the present one using different primers and relevant groups of organisms before  
437 embarking on metabarcoding experiments.

438 The model has implicitly assumed that all species in the mixture are amplified to some extent  
439 in the simulated PCR. This assumption is at odds with the fact that all primers fail to amplify  
440 some species (Brandon-Mog et al., 2015; Mao et al., 2012). This is of little importance in our  
441 approach. If some species fail to amplify its final concentration would be  $f_i = 0$ ; in our model  $f_i$   
442 would be a very small number, but never 0. However, as we calculate the linear correlation  $\rho_{f_i}$   
443  $f_i$  without any transformation of the raw data, the fact that  $f_i$  is 0 or a very small number like,  
444 let's say 0.00001, is of minor importance.

445 It is also important to mention that, implicitly, we considered that the initial DNA concentration  
446 was proportional to some measure of abundance, like biomass or individual number, but this  
447 is not necessarily the case, especially when multiple-copy markers are used. In plants, there  
448 is the added problem of ploidy. Unfortunately, interspecific comparisons using single copy  
449 nuclear markers are not usually viable in dietary analysis, as multi-copy targets are needed to  
450 amplify the degraded DNA associated with herbivory and predation. In addition, whilst there is  
451 some information about gene copy number across taxa in prokaryotes (i.e., 16S rRNA gene;  
452 Farrelly, Rainey, & Stackebrandt, 1995), and even ways to use this information for *a posteriori*  
453 correction of read numbers (Angly et al., 2014), we are not aware of any reliable data on  
454 mtDNA copy number across arthropod species.

455 Despite the overwhelming complexity of the entire metabarcoding process (Figure 1), the  
456 model presented here offers some hope for making the process more quantitative. By simply  
457 choosing a primer set with a low variance in the number of mismatches it is possible to obtain  
458 greater quantitative accuracy. It is true that other sources of bias remain unchanged, like  
459 different digestion rates for DNA from different species, but the results presented here would  
460 help to reduce the overall bias.

461

649

## 650 **Authors contribution**

651 JP, MAS, and WOCS designed the study. JP and MAS wrote the code and performed the  
652 statistical analyses. All authors played a role in editing the final version of the paper.

653

## 654 **Data Accessibility**

655 The mitochondrial genomes and the R scripts used to generate the results are archived in  
656 Dryad (doi:10.5061/dryad.q2r3b1f).

657

## 658 **Supporting information**

659 Additional supporting information may be found in the online version of this article.

660 **Figure S1.** Distribution in orders of the species of insects used in the study.

661 **Figure S2.** (A) Histogram of the best fitting  $k$  values of a geometric distribution.

662 **Figure S3.** Effect of the species richness ( $S$ ) on the 95% confidence interval (95% CI) for the  
663 Pearson correlation coefficient  $r$ .

664 **Figure S4.** Effect of the parameter  $k$  of the geometric distribution on the 95% confidence  
665 interval (95% CI) for the Pearson correlation coefficient  $r$ .

666

**Table 1.** A compilation of experiments attempting to establish whether DNA metabarcoding can be said to be quantitative. The goodness of fit was usually estimated as the Pearson or Spearman squared correlation coefficient; its significance is given as NS ( $P > 0.05$ ), \* ( $P < 0.05$ ), \*\* ( $P < 0.01$ ), and \*\*\* ( $P < 0.001$ ).

675

676

677 **Table 4.** Proportion of runs in which the same species is most abundant both before and  
678 after the simulated PCR reaction for Model 1 and Model 2 simulations. Proportion based  
679 on 10000 simulation runs per primer pair. It is indicated in bold face whether it is safe (at  
680  $\alpha = 0.95$ ) to conclude which species is the most abundant in the mixture.

Primer pair	Model 1	Model 2
1	0.42	0.65
2	0.43	0.51
3	0.42	0.94
4	0.49	0.41
5	0.36	0.50
6	0.55	0.85
7	0.63	0.76
8	0.52	0.94
9	0.53	0.67
10	0.94	<b>1.00</b>
11	0.88	<b>0.98</b>
12	0.81	<b>0.98</b>
13	0.91	<b>0.97</b>
14	0.79	<b>1.00</b>

681

682

683      **Table 5.** Percentage of the variance in the linear correlation coefficient  $r$  explained by  
684      each parameter involved in the simulations using models 1 and 2.

Factor	Model 1	Model 2
Primer pair (pp)	23.0	20.9
S	0.1	0
k	11.8	2.2
$\beta$	2.0	0
pp:S	0	0
pp:k	0.9	0.9
pp: $\beta$	0.2	0
S:k	0	0
S: $\beta$	0	0
k: $\beta$	0	0
unexplained	62.0	76.0

685

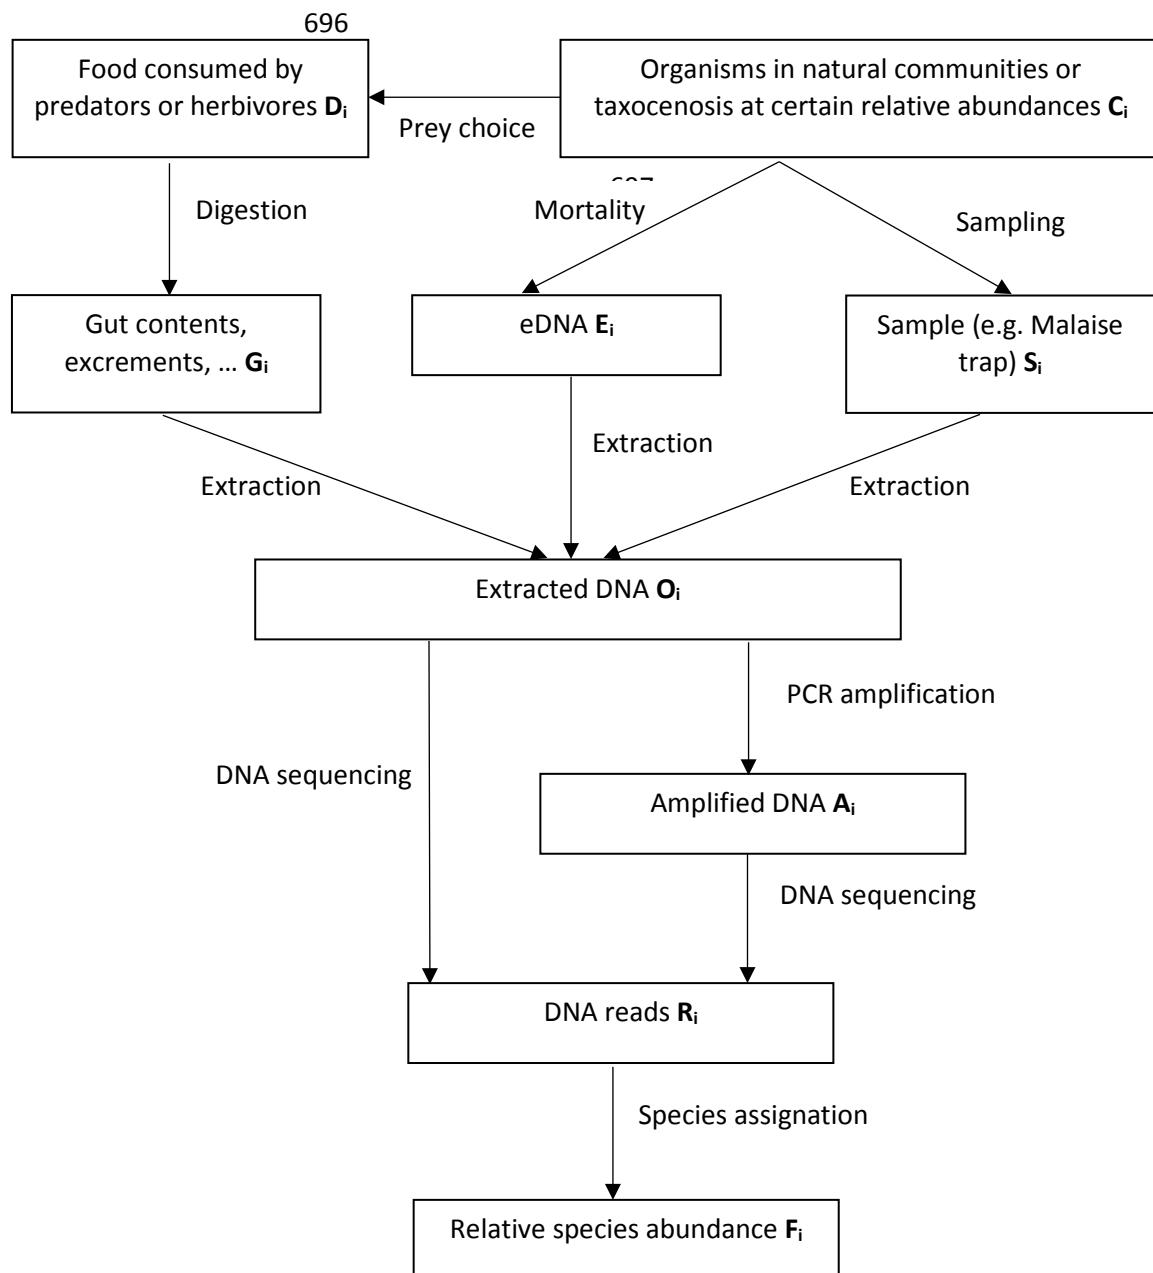

686   **Table 6.** Two hypothetical mixtures of ten species, with the number of mismatches of  
 687   each species, its original and final DNA concentration ( $o_i$  and  $f_i$ ), and its amplification  
 688   efficiency ( $\beta = 4$ ). The mixture B is the same as the mixture A, but for the swap of  $o_i$  of  
 689   species #1 and #8.

<b>A</b>				
#sp	$m_{Ti}$	$o_i$	$e_i$	$f_i$
1	0	0,403	1,000	0,437
2	0	0,241	1,000	0,261

690

691   **Figure 1.** Conceptual diagram of the process of quantitative DNA metabarcoding, from  
 692   the usual targets (relative abundance of diet components,  $D_i$ , or species in a community  
 693    $C_i$ ) to the final assignment of abundances to species ( $F_i$ ). The sub index  $i$  indicates the  
 694   abundance of species  $i$  in the multispecies mixture. This study covers the process of  
 695   amplicon metabarcoding ( $O_i \rightarrow A_i \rightarrow R_i$ ).

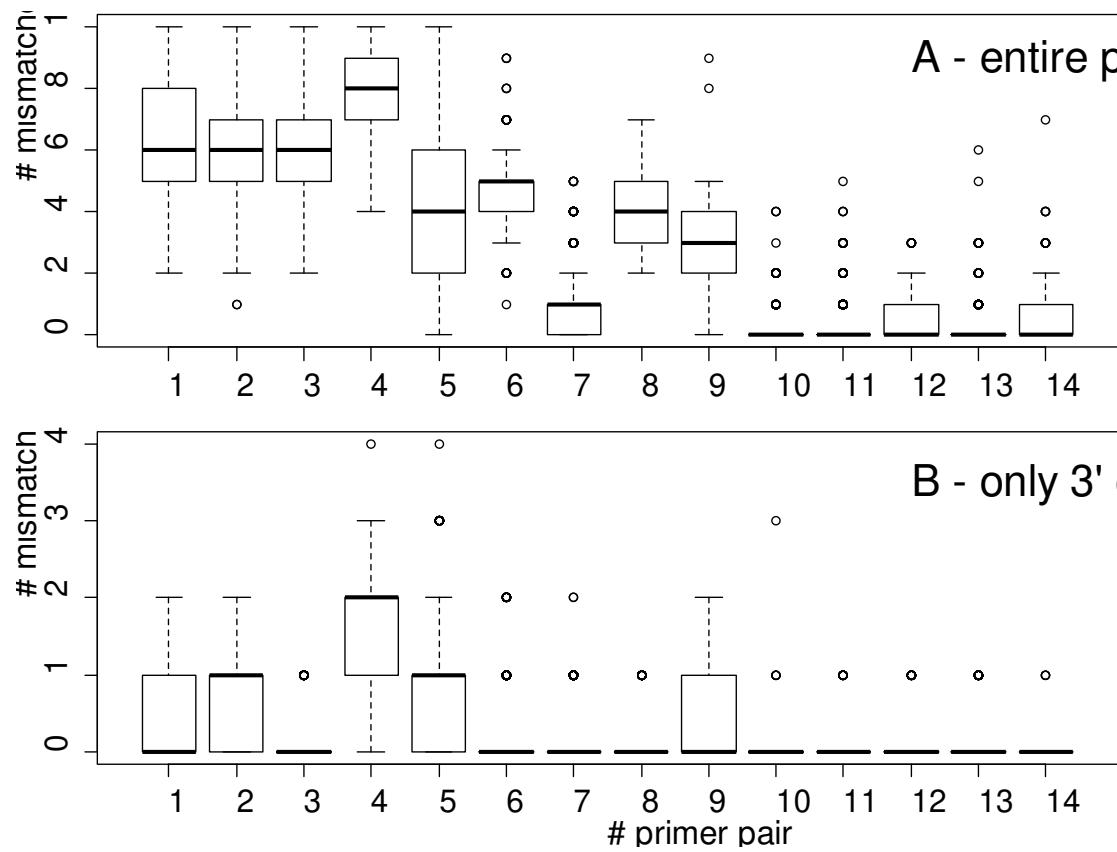

698      **Figure 2.** Flow diagram of the pipeline used in this study. On the left-hand side,  
699      calculations of template-primer mismatches for each primer pair and genome, both for  
700      all the nucleotides in both the forward and reverse primers ( $m_T$ ; model 1) and only on  
701      five 3'-terminal nucleotides ( $m_5$ ; model 2). On the right-hand side, the algorithm that  
702      generates random mixtures of species at random initial abundances ( $o_i$ ), estimates an  
703      amplification efficiency for each species based on the number of template-primer  
704      mismatches, and simulates a PCR reaction to produce a final relative abundance of each  
705      species ( $f_i$ ).  
706

707      ..... run once .....      ..... run many times .....

713 **Figure 3.** Boxplot of number of template-primer mismatches for each primer pair. (A)  
714 Model 1 considers the total number of mismatches in both the forward and reverse  
715 primers. (B) Model 2 considers only the mismatches in the five 3'-terminal positions of  
716 both primers. Primer pair numbering is the same as in Table 3.

717

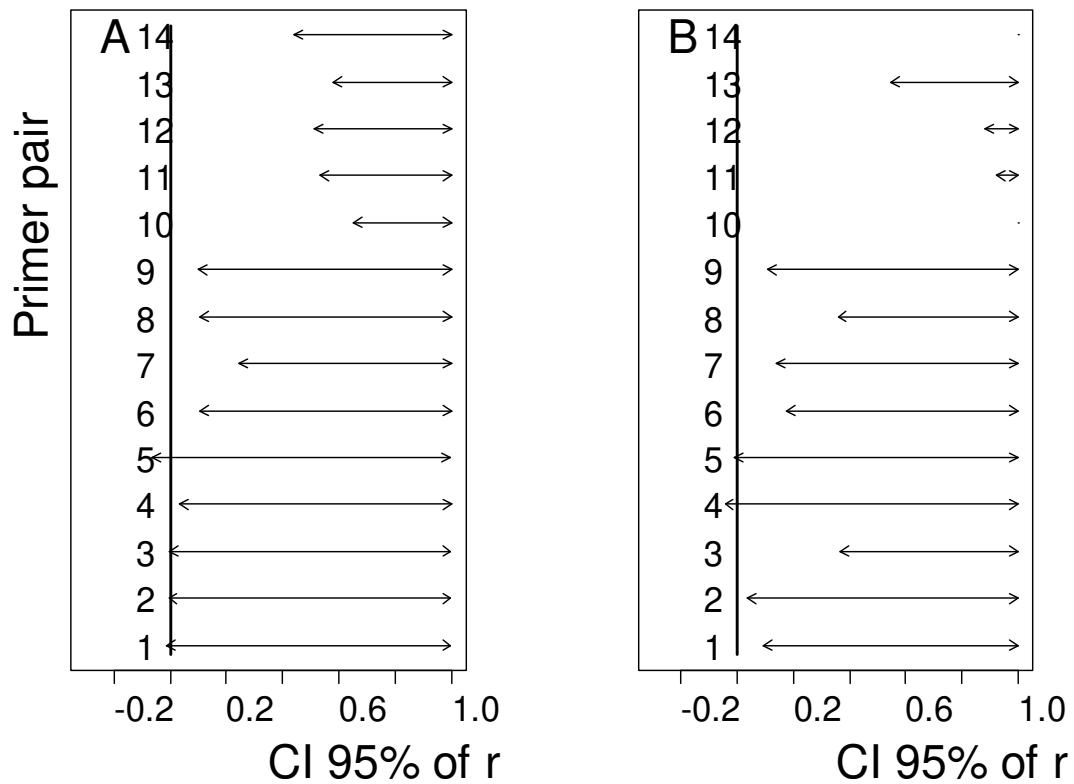

718

719

720

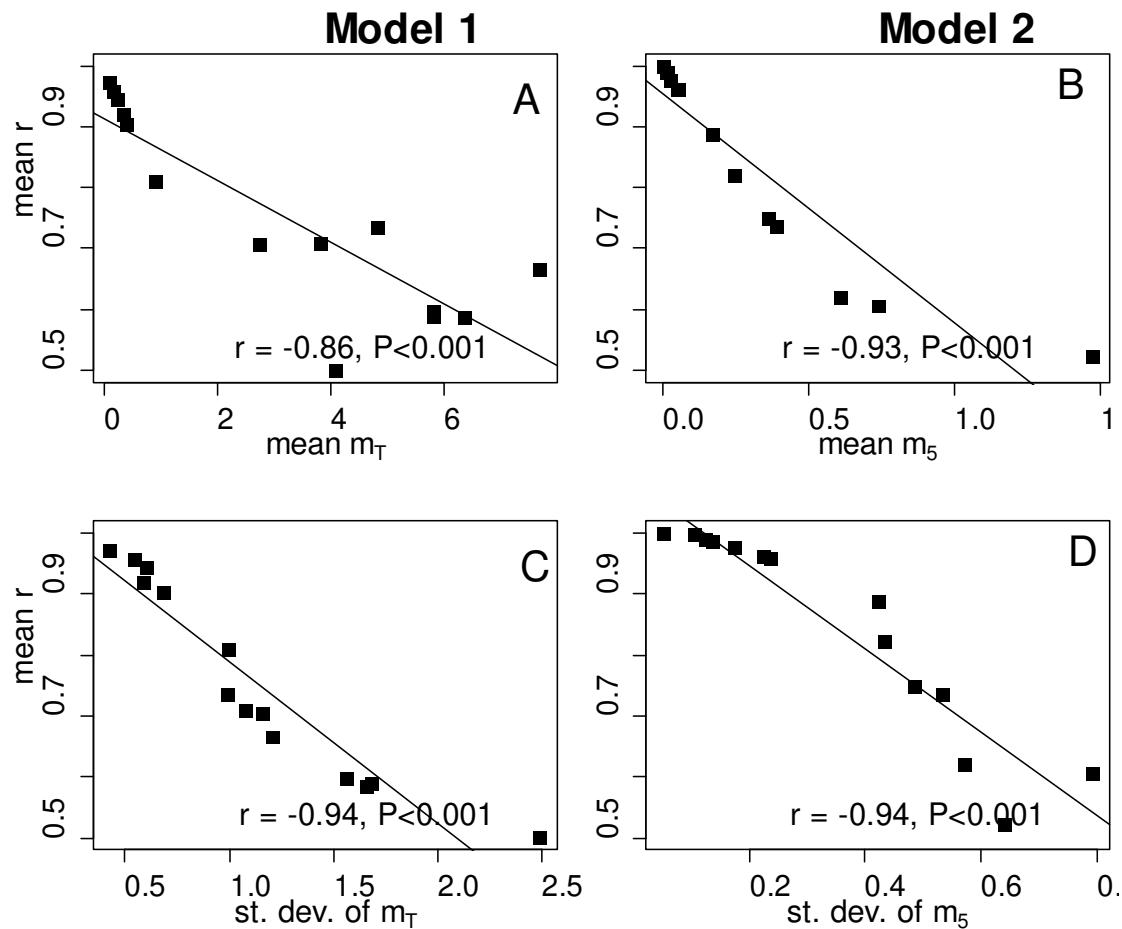

721 **Figure 4.** Ninety-five percent confidence interval (95% CI) for the Pearson correlation  $r$   
722 for each primer pair analysed for Model 1 (A) and Model 2 (B). For primer pairs #10 and  
723 #14 in B, the CI is so small that the arrowheads could not be plotted. When the CI cuts  
724 the vertical line at  $r = 0$  it indicates that it is not possible to consider that  $r > 0$  (with a  
725 probability of 0.95). Primer pair numbering is the same as in Table 3.

726

727

728 **Figure 5.** Relationship between the simulated mean of  $r$  and the mean number of  
729 template-primer mismatches (A, B) and the standard deviation of the number of  
730 mismatches (C, D) for model 1 (A, C) and model 2 (B, D);  $m_T$  = number of mismatches  
731 in the entire length of both primers;  $m_5$  = number of mismatches in the five 3'-end  
732 positions of both primers.

733
