ABSTRACT: We report on the self-assembly of a conformational flexible organic compound on Au(111) using scanning tunneling microscopy and low-energy electron diffraction measurements. We observed different conformers of the compound upon adsorption on the reconstructed Au(111) surface. Increasing the molecular coverage enhanced the lateral pressure, that is, parallel to the surface, favoring a coverage-controlled transition from a supramolecular network displaying only one molecular organization, into a polymorphic array with two coexisting arrangements. Our results give insights into the role of substrate-induced conformational changes on the formation of polymorphic supramolecular networks.

1. INTRODUCTION

Two-dimensional (2D) self-assembly of molecules on surfaces has been widely employed to fabricate functional, supramolecular networks in a bottom-up fashion.1–3 Steering the self-assembly toward a programmed supramolecular structure is often done through careful selection of the functional end groups of the molecular building blocks, and its control is very important if one wants to achieve functional properties both as 2D or three-dimensional functional materials.4–11 However, surface-confined molecular assemblies can exhibit an energetic equivalence of different structures, leading to polymorphism, that is, the simultaneous presence of different isoenergetic arrangements for the same compound. Transitions between those arrangements can be promoted, inter alia, by altering the number of substituents for the molecular compound,12 adsorbing the same compound on a different substrate,13,14 providing energy by means of annealing of the sample,15,16 varying the molecular coverage,17–20 or a combination of these factors.21–23

In this study, we report on the coverage-controlled self-assembly of a linear molecule on Au(111). For the formation of well- and long-range-ordered structures, we deployed molecular recognition based on H-bonding between substituted functional groups. For this purpose, H-bonding is commonly used because of its versatility, selectivity, directionality, and possibility of engineering complementary recognition motifs.24,25 Linear molecule 1 used in our study bears two terminal 2,6-di(acetylamino)pyridyl (DAP) recognition sites linked via a central 1,4-diethynyl benzene (Scheme 1a). Although the trans conformation for the amide functional groups (Scheme 1b) is the most stable in the gas phase,26 other conformations can be however observed when adsorbed on the surface. When all amides are in trans conformation, the moiety can form triple H-bonds with suitable uracyl partners and lead to DAD···ADA-type (D and A stand for donor and acceptor, respectively) H-bonded heterodimeric arrays. However, when one or both amides are frontal-trans conformation, homodimerization is possible through the formation of quadruple H-bonded dimers (DADA)₂ and (ADADA)₂.27,28 However, when the DAP is folded in a frontal-cis conformation, no dimers can be formed and these conformations are usually the most unstable because of steric clashes and electrostatic repulsions.

The conformational flexibility of the DAP moiety has allowed the successful formation of various self-assembled structures on the surface and, at that time, the first trimeric supramolecular heterocomplexes on Ag(111) under ultrahigh vacuum (UHV) conditions.29 At the solid–liquid...
interface, molecule 1 enabled the engineering of tricomponent nanopolygons and porous networks.33,34

Herein, we observed conformational changes upon adsorption on the Au(111) surface as a result of the conformational dynamicity. Moreover, the presence of different conformers allowed the formation of two isoenergetic supramolecular arrangements. Intriguingly, no complete conversion from one arrangement into the other could be achieved. Instead, by controlling the molecular coverage, we were able to transform the monomorphic network expressing one arrangement into a polymorphic assembly, expressing two coexisting molecular arrangements. The observed behavior and arrangements on Au(111) were considerably different from those of the same compound on Ag(111) at elevated temperatures, as the frontal-cis conformer was formed this time and a polymorphic arrangement is observed.31

2. METHODS

2.1. Sample Preparation. We prepared Au(111) by repeated cycles of sputtering with Ar+ ions and subsequent annealing at 800 K under UHV conditions. Molecules were prepared following the literature procedure32 and sublimed at 490 K onto the sample using a Knudsen cell evaporator (home-built). During deposition, the sample was kept at room temperature (RT). Some samples were annealed after molecule deposition, which will be explicitly indicated throughout the text. We define one monolayer (ML) as the coverage for which the substrate is fully covered by molecules in the densest possible arrangement.

2.2. Scanning Tunneling Microscopy and Low-Energy Electron Diffraction Measurements. We performed our experiments in a UHV system with two chambers. The first chamber hosted a low-temperature scanning tunneling microscopy (STM) setup (Scienta Omicron GmbH) and had a base pressure of <5 × 10−11 mbar. The second chamber had a base pressure of <1 × 10−10 mbar and was equipped with a multichannel plate low-energy electron diffraction (LEED) system (Scienta Omicron GmbH) as well as the Knudsen cell evaporator. The samples were at RT for LEED measurements, whereas STM measurements were performed at 77 K. We used tips made from mechanically cut Pt/Ir wire to obtain STM images in constant current mode. All voltages are given with respect to a grounded tip. We processed the STM images using the software WSxM.35

3. RESULTS AND DISCUSSION

3.1. Molecular Arrangements of 1 on Au(111). Figure 1a depicts an STM image of the self-assembly of 1 on Au(111) for a coverage below 0.5 ML. The sample was measured directly after molecule deposition, that is, without any annealing. We observed no long-range order. Molecules

The Journal of Physical Chemistry C

Figure 1. Self-assembly of 1 on Au(111) in dependence of molecular coverage and annealing temperature. (a) STM image for a coverage below 0.5 ML (80 × 80 nm², −1.5 V, and 30 pA). The sample was prepared without annealing after deposition at RT. (b) High-resolution STM image (20 × 20 nm², −0.6 V, and 80 pA) of the same sample shown in (a). For coverages below 0.5 ML, the molecular arrangement α was exclusively present. (c) STM image of the sample shown in (a,b) after annealing at 370 K (80 × 80 nm², 1.2 V, and 20 pA). Compared to (a), the island size is significantly increased (80 × 80 nm², 1.2 V, and 20 pA). We still only observed arrangement α. (d) STM image for close to 1 ML coverage prepared without annealing (80 × 80 nm², 1.2 V, and 20 pA). Compared to (a), the island size is significantly increased (80 × 80 nm², 1.2 V, and 20 pA). We still only observed arrangement α. (e) STM image of a sample similar to (d,e) after annealing at 370 K (100 × 100 nm², 1.0 V, and 20 pA). For both arrangements, the island size increased.
arranged into small patches that seemed to nucleate at the elbow sites of the Au(111) reconstruction. A high-resolution STM image of the same sample (Figure 1b) reveals that molecules assembled in only one arrangement, labeled as α. Annealing the same sample to 370 K yielded an increased long-range order, that is, larger islands of molecules were present (Figure 1c). Notably, we still observed arrangement α exclusively.

Figure 1d shows an STM image of a sample with coverage close to 1 ML before annealing, and no long-range order was observed. In contrast to the sample with low coverage (Figure 1a), we found different arrangements. In addition to arrangement α, a high-resolution STM image shows a second network, labeled β (Figure 1e). Annealing to 370 K again induced long-range order (Figure 1f). Both arrangements α and β coexisted on the surface and showed increased island sizes when compared to the unannealed samples (Figure 1d).

Independent of coverage or temperature, the unmodified herringbone pattern of the reconstructed 22 × √3—Au(111) surface can be seen through the arrangement.

Figure 2a shows a high-resolution STM image of arrangement α. The rectangular unit cell is drawn in green, and a model of one molecule is overlaid to guide the eye. The principal directions of the Au surface are indicated by black lines in Figure 2a. The length of the unit cell vectors are a = 5.0 nm and b = 3.0 nm, and the angle is Θ = 90°. The unit cell contains six molecules, which results in a molecular density of 0.40 molecules/nm². The long axis of the unit cell is furthermore parallel to the [110] direction of the Au(111) surface as shown in the tentative structural model (Figure 2b). We observed both trans and frontal-cis conformations which can be identified due to the different opening angles of the DAP site of 1 resulting in a different fingerprint in the STM images. Specifically, four molecules showed a combination of trans and frontal-cis, and the other two had all amides in the trans conformation. Figure 2a–c shows a set of high-resolution STM images of the different conformations of 1 found in arrangement α. Additionally, we observed the molecular backbone bent for most of the molecules in the unit cell, that is, a distortion of the acetylenic linkers resulting in a deviation of the C=C bond angle from the common 180°. Similar bond isomers have also been observed for ethynyl-bearing porphyrins.37 Arrangement α is stabilized by double H-bonding interactions (marked orange, yellow, and magenta in Figure 2b).

Figure 2c shows a high-resolution STM image of arrangement β. The rhombic unit cell is displayed in cyan, and a pair of molecules is overlaid to guide the eye. We measured a = b = 4.0 nm for the length of the unit cell vectors and an angle of Θ = 120°. The unit cell again contains six molecules, leading to a molecular density of 0.44 molecules/nm². The unit cell is slightly rotated by γ = ±8° with respect to the [110] direction of the Au(111) surface (Figure 2d). All six molecules in the unit cell exhibit a combination of trans and frontal-cis conformations of their H-bonding recognition sites. A high-resolution STM image of this combination of conformations is shown in Figure 3a,c. We did not observe any bending of the molecular backbone. Arrangement β is stabilized with a combination of different H-bonding motifs. For each molecule, one DAP unit, for which the amides are in the trans conformation, binds to three neighboring molecules in the following fashion: two times via double H-bonding (marked orange) and one time via a single H-bond (marked green). The other DAP unit, for which one amide is in the trans conformation and the other one is in the frontal-cis conformation, also engages in H-bonding with three other molecules. However, it does so via a cyclic trimeric motif with two neighboring molecules (marked black) and a single H-bond with another neighboring molecule (marked green). A summary of the properties of arrangements α and β is shown in Table S1.

We gained complementary insight into the arrangements of 1 on Au(111) using LEED. Figure 4a shows a LEED pattern for a sample with close to 1 ML coverage after annealing it at 370 K for 30 min. We observed clear diffraction spots for several orders of diffraction. Figure 4b,c shows the simulated LEED pattern of arrangements α and β, respectively. Combining and overlaying these onto the measured LEED pattern (Figure 4d) results in a good agreement. The LEED data corroborate the observations made in STM: (i) arrangement β exhibits indeed a rotation of γ = ±8° with respect to the [110] Au direction and (ii) the good long-range order of both molecular structures after annealing.

Up to this point, we observed arrangement α exclusively at coverages below 0.5 ML, whereas at higher coverages, arrangements α and β coexisted. We saw that annealing the sample at 370 K had no influence on this polymorphism and
only led to increased long-range order. Annealing samples above 400 K led to a decrease of island size coinciding with an increasing amount of disordered structures that followed the herringbone reconstruction as well as defective molecules (Figure 5a,b). After annealing at 470 K, we observed one-dimensional chains and decorated step edges (Figure 5c). We suggest that 1 decomposed at temperatures above 400 K.

Additional to coverage and annealing, we also studied the influence of other sample preparation parameters. We therefore prepared samples with molecular deposition rates between 0.1 and 1 ML/min. Furthermore, we varied the cooldown rate of the sample after annealing. This was achieved by either cooling the sample down to 77 K immediately after annealing or leaving it cooling down to RT first, followed by cooling down to 77 K. We found no influence on the individual arrangements or their coexistence (Table 1). This suggests that the polymorphism of 1 is neither kinetically driven nor a result of quenching.

### 3.2. Discussion

We will discuss our findings in light of a previous study of molecule 1 on Ag(111). In this study, compound 1 formed a porous network stabilized by double H-bonding upon deposition on the Ag(111) surface.31 In this network, all amide functional groups were in the most stable trans conformation. Upon annealing, one amide group rotated around the CO···NHR bond into a cis conformation (Scheme 1 and Scheme S1c), enabling quadruple H-bonding per binding DAP site. This resulted in a second, densely packed arrangement. Both arrangements were exclusively present and only dependent on the temperature. The results of this study contrast with the behavior of 1 on Au(111) in three aspects: (i) conformation of 1, (ii) temperature dependence, and (iii) coverage dependence.

In contrast to 1 on Ag(111), we found conformational changes of 1 already upon adsorption on Au(111) at RT. Therefore, the reconstructed Au(111) surface seems to be instrumental in facilitating the conformational changes of 1. Although our calculations for adsorption of single molecules on Au(111) show that the trans conformation is energetically slightly favored in comparison to the frontal-cis one (Figure 6), we suggest that this energy penalty is overcome by the formation of intermolecular interactions that are established in the network. A similar conformational dependency on the underlying substrate has previously been observed for flexible substituents of a porphyrin derivative.38 Furthermore, relativistic effects have been shown to significantly influence the orbitals of Au atoms, resulting in the emergence of different self-assembly structures on Au(111) compared to Ag(111).39

Temperature can commonly be used to induce conformational changes of molecules resulting in a transformation of the molecular arrangement.15,16,40 For 1 on Ag(111), the conformational changes caused by annealing resulted in a transformation from one arrangement to the other.31 This observation stands in contrast to the observations for 1 on Au(111). Annealing our samples only led to increased longer-range order followed by decomposition of the compound at very elevated temperatures. We did not observe any influence of the temperature on either the conformation of 1 or the formation of arrangements α or β. Attempts to drive one arrangement into the other or possibly a different, third arrangement by means of temperature were also unsuccessful. We can infer from these observations that (i) the energy barrier between arrangements α and β is higher than the energy needed for decomposition and (ii) no third arrangement exists that is thermodynamically favored and accessible. The first point is also supported by our transition-state calculations (Figure S1) which identify an energy barrier of 1.25 eV between conformations A and B. It should be noted however that a low-energy barrier combined with a significant energetic difference between α and β could equally support our observation. Coverage has often been reported to promote transitions between different structures of a polymorphic system.23,41–43 In cases of flexible molecules, this coverage-induced transition can go along with a conformational change of the molecules.44–48 Although no coverage dependence has been reported for 1 on Ag(111), increasing the lateral pressure by means of molecular coverage was the sole driving factor for observing polymorphism of 1 on Au(111). Arrangement β emerged for coverages above 0.5 ML. In contrast to arrangement α, molecules in arrangement β notably did not exhibit any bending. However, all molecules in arrangement β featured a conformational change, that is, exhibited amides both in their trans and frontal-cis conformations. Although this is certainly associated with an energy penalty, arrangement β exhibited an increased density, thus minimizing the surface free energy more efficiently than the less dense arrangement α. We furthermore were unable to achieve a complete transition from arrangement α into arrangement β. Instead, both arrangements coexisted above the threshold coverage of 0.5 ML and furthermore grew in a uniform fashion until 1 ML was reached, that is, at all time, arrangement α was dominant.

4. CONCLUSIONS
In conclusion, we studied the self-assembly of a linear molecule with conformationally flexible H-bonding recognition sites on Au(111). We observed conformational changes upon adsorption on the reconstructed Au(111) surface. By controlling the coverage, we were able to transform a monomorphic array expressing one molecular arrangement into a polymorphic system with two coexisting molecular arrangements. The polymorphism itself was unaffected by variation of other preparation parameters including temperature, making the molecular coverage the sole driving force of the mono- to polymorphic transition. These results stand in contrast to previous findings for the same molecule on Ag(111), for which a net transition between two molecular organizations was observed. Our findings not only illustrate the role of conformational changes in polymorphic supramolecular networks but also showcase how molecules with high conformational flexibility can be used to achieve different self-assembled architectures on structurally similar surfaces.
