A novel system for the classification of diseased retinal ganglion cells

Abstract
Retinal ganglion cell (RGC) dendritic atrophy is an early feature of many forms of retinal degeneration, providing a challenge to RGC classification. The characterisation of these changes is complicated by the possibility that selective labelling of any particular class can confound the estimation of dendritic remodelling. To address this issue we have developed a novel, robust and quantitative RGC classification based on proximal dendritic features which are resistant to early degeneration.

RGCs were labelled through the ballistic delivery of DiO and Dil coated tungsten particles to whole retinal explants of 20 adult Brown Norway rats. RGCs were grouped according to the Sun classification system. A comprehensive set of primary and secondary dendrite features were quantified and a new classification model derived using principle component (PCA) and discriminant analyses, to estimate the likelihood that a cell belonged to any given class.

One-hundred and thirty one imaged RGCs were analysed; according to the Sun classification 24% (n=31) were RGC_A, 29% (n=38) RGC_B, 32% (n=42) RGC_C and 15% (n=20) RGC_D. PCA gave a 3 component solution, separating RGCs based on descriptors of soma size and primary dendrite thickness, proximal dendritic field size and dendritic tree asymmetry. The new variables correctly classified 73.3% (n=74) of RGCs from a training sample and 63.3% (n=19) from a hold out sample indicating an effective model.

Soma and proximal dendritic tree morphological features provide a useful surrogate measurement for the classification of RGCs in disease. While a definitive classification is not possible in every case the technique provides a useful safeguard against sample bias where the normal criteria for cell classification may not be reliable.

Key words: Retinal ganglion cells, Classification, Rat, Retinal degeneration
Introduction

Inner retinal degeneration, in particular of the retinal ganglion cells (RGCs), is a hallmark of glaucoma (Qu et al., 2010) and of interest in many retinal diseases (Barber et al., 1998; Votruba et al., 1998; Williams et al., 2010). The study of RGC morphological and functional changes is vital in understanding disease progression and visual outcomes. While the primate provides the closest match to the human eye, the rat and mouse offer more tractable models for studying retinal degeneration.

Electrophysiological and morphological studies of single retinal ganglion cells have revealed the functional and structural basis for the classification of RGCs. The matching of Boycott and Wassle’s (Boycott & Wassle, 1974) morphologically described cat α and β cells to Enroth-Cugell and Robson’s functionally described cat Y and X cells (Enroth-Cugell & Robson, 1966) highlighted the close relationship between structure and function in RGCs. The intrinsic electrical properties of the cat RGC are robust indicators of RGC type (O’Brien et al., 2002). RGC receptive field sensitivity maps to the dendritic field as a function of bipolar cell connectivity (Brown et al., 2000).

The shape and branching of the dendritic tree has been used to define the sub classification of RGCs in healthy adult and developing retina. The morphological classification of RGC types in the cat (Hochstein & Shapley, 1976; Citron et al., 1988; Coelho et al., 2002), primate (Peichl, 1991; Dacey, 1993), mouse (Sun et al., 2002b; Coombs et al., 2006) and rat (Huxlin & Goodchild, 1997; Sun et al., 2002a) is comprehensive, with many cells matching functionally described types.

By contrast, RGC classification in retinal degenerative diseases where the dendritic architecture is altered remains problematic. Recent studies have reported reductions in dendritic field size and branching density in diseased RGCs (Weber et al., 1998; Shou et al., 2003; Leung et al., 2011; Kalesnykas et al., 2012; Feng et al., 2013). The classification of RGCs by these same measurements (dendritic field diameter, branching density and stratification) may be unreliable in disease states particularly in rodent eyes where the
features defining RGC classes can be subtle. Without classification, bias in the labelling of any given RGC type could show artifactual shrinkage or recovery of the dendritic tree following treatment.

In this study we explore the possibility that a robust RGC classification system can be based on dendrite features that are relatively resistant to the effects of early disease. We base this on the observation that early to moderate RGC damage consistently affects tertiary dendrites, leaving more proximal dendritic structures intact (Weber et al., 1998; Morgan et al., 2006; Williams et al., 2010). This concept is illustrated in Figure 1 based on modelling of typical Sholl profiles in normal and diseased tissue (Weber et al., 1998; Morgan et al., 2006; Williams et al., 2010).

Our hypothesis is that a new set of parameters based on primary and secondary dendrite features can be used to indicate the class composition of a population of labelled RGCs from diseased retinas and act as a check against the selective labelling of cells from any given class. We therefore determined the extent to which structural features of primary and secondary dendrites could be used to separate cell types and derive a new classification system.
Methods

Experiment procedures were conducted in accordance with the guidelines of the Society for Neuroscience and Home Office (UK) regulations governing the use of animals in research.

DiOlistic labelling

Twenty retired breeder Brown Norway rats, aged 4-6 months, were killed by overdose of CO₂. Death was confirmed by cervical dislocation and the eyes immediately enucleated. The retinas were dissected in Hank’s balanced salt solution (Life Technologies, US) and orientated using a cut in the nasal quadrant. Dissected retinas were flat mounted on cell culture inserts (Millipore 0.4µm pore, Fisher Scientific, US) and DiOlistically labelled following a modified protocol of Gan (Gan et al., 2000). A Helios gene gun (BioRad, US) was used to fire 1.7µm tungsten particles coated with 1,1'-Dioctadecyl-3,3,3',3'-Tetramethylindocarbocyanine Perchlorate (DiI) and 3,3'-Dioctadecyloxacarbocyanine Perchlorate (DiO) (both Life Technologies, US) into the retina at 689.5 kPa (100 psi) and a gun nozzle to retinal surface distance of 4cm. Aggregated particles were excluded by placing a cell culture insert (BD Falcon 3.0µm, BD Biosciences, US) between the retina and gene gun. Retinas were then cultured in Neurobasal-A medium for 30 minutes at 37°C. Retinas were flat mounted ganglion layer up on Histobond® coated slides (Fisher Scientific, US), fixed with 4% paraformaldehyde (pH 7.4) for 20 minutes and washed with phosphate buffered saline (PBS). TO-PRO-3 Iodide (Life Technologies, US) diluted 1:1000 in PBS was applied for visualisation of ganglion cell and inner nuclear layers in order to measure stratification of RGCs in the inner plexiform layer (IPL). Retinas were then mounted in ProLong® gold antifade reagent (Life Technologies, US). A Zeiss LSM 510 confocal microscope (Carl Zeiss AG, Germany) with a x20 air objective (NA 0.8) was used to capture multichannel z-stack images (1024x1024 pixels, 0.54µm/pixel, slice thickness 1µm) of single DiI and DiO labelled RCCs, with TO-PRO-3 stained ganglion cell to inner nuclear layers. RGC distance from the optic nerve in the x and y plane was recorded using a custom scanning stage attached to the microscope.
Analysis of new RGC parameters

Only those RGCs with an axon traceable towards the optic nerve and a dendritic tree easily distinguishable from those of other cells were included. In addition RGCs whose primary dendrite origin at the soma was obscured was not included. In the analysis the following dendrite parameters were determined:

- The number of primary dendrites (PD) – i.e. those originating directly from the soma.
- The distance from the soma to the primary branch point was measured for each primary dendrite using the simple neurite tracer plugin (Longair et al., 2011) in Fiji (Schindelin et al., 2012) and a mean primary dendrite length (PDL) given for each cell.
- Primary branch point field (PBPF) area – In Z-collapsed images the primary branch points were connected and the area of the resultant field measured to give the PBPF area.
- PBPF centre of gravity offset (CGO) from the soma - As a measure of asymmetry in the dendritic tree the PBPF’s centre of gravity offset from the soma was measured. The PBPF centroid was found and its distance from the soma centre measured. This was expressed as a percentage of the diameter of the PBPF to account for RGC size variation.
- Secondary branch point field (SBPF) area
- SBPF centre of gravity offset (CGO) from the soma
- PD asymmetry - As a further measure of asymmetry, the distribution of primary dendrites about 360° of the cell soma was measured using the oval profile plugin in Image J (NIH, US). In Z-collapsed images a circle with a radius of 25µm from the soma centre was drawn, and the angle at which each primary dendrite intersected the circle measured. The angle formed between the primary dendrite immediately clockwise and counter clockwise of the axon was taken so that a larger angle would represent greater asymmetry in the PBPF.
- Proximal branching density – As a measure of branching density in the proximal dendritic tree the PBPF area was expressed as a percentage of the SBPF area.
- Soma diameter - RGC soma diameter was also measured by drawing a polygon around the soma in Z-collapsed images, the resulting area was converted to a circle and the diameter calculated.
- Distance of RGC soma in X and Y plane from the optic nerve head (ONH) centre, also expressed as a vector length.
- PD cross-sectional area – As a measure of primary dendrite thickness at the origin from the soma, primary dendrite traces derived from the simple neurite tracer plugin were re-sliced to give a cross-sectional view and the area at the origin measured.
- PD Feret diameter – As a further measure of dendrite thickness, the minimum and maximum Feret diameters of the re-sliced dendrite were measured.

Comparison to existing classification

RGCs were classified according to Sun (Sun et al., 2002a) on the basis of dendritic field diameter, dendrite stratification within the IPL, soma diameter and branching density. Sholl analysis using FastSholl plug-in (Gutierrez & Davies, 2007) for MATLAB (MathWorks, US) was conducted on all cells. Cells were grouped according to Sun (Sun et al., 2002a) and the mean and SD of the new parameters was calculated for each resulting group. A principal component analysis (PCA) was then performed in SPSS (version 18.0, IBM, US) to reveal factors driving separation and a discriminant analysis (SPSS) performed in order to reveal if the new parameters could classify into the same groupings as Sun. RGCs were randomly assigned to either a training data sample or hold-out sample. Each RGC was assigned a random number from a chi-square distribution with 1 degree of freedom using the random number generator function in SPSS. RGCs were then sorted by size of random number in ascending order with the first 30 RGCs assigned to a hold-out sample and the remaining 101 RGCs to the training sample.
Results

RGC imaging and Sun classification

One-hundred and thirty one RGCs from 20 retinas imaged were included in the analysis based on the described exclusion criteria. The retinal locations of 114 RGCs are shown in Figure 2 (the locations of 26 cells were not measured). The mean Sholl profile for each RGC type is plotted in Figure 3. Classification according to (Sun et al., 2002a) criteria gave comparable percentages of cell types in the overall population, reported here as present study percentage (Sun percentage), at 24% (18%) RGC_A, 29% (30%) RGC_B, 32% (36%) RGC_C and 15% (18%) RGC_D. Our sample therefore provides a similar breakdown of the RGC population for the derivation of classification parameters. The mean and standard deviation according to Sun type for all classification parameters measured are detailed in Table 1. Typical cells for each of the 4 classes are shown in Figure 4.

Retinal eccentricity does not affect classification

One-way ANOVA with post-hoc Bonferroni showed no significant difference between RGC types with respect to retinal eccentricity when expressed as vector length (P>0.05). This confirmed that labelling was not regionally biased. RGC distance from the ONH centre expressed as distance in x, y and vector distance all showed no correlation to any variables (P>0.05) demonstrating that retinal eccentricity had no effect on variable measurements. The classification of RGCs into types according to Sun was also unaffected by retinal eccentricity as dendritic field diameter and soma diameter showed no correlation to vector length (P>0.05, Pearson’s correlation).

RGCs differ in size and asymmetry of the proximal dendritic tree

A PCA was performed in order to determine the variables that contribute to the variation in morphology between RGC types and are thus the most useful in discriminating RGC types. PCA loses power and relevance if variables included are not correlated. RGC distance from the ONH in the x and y plane and as vector length were all discarded as variables due to the
lack of correlation (as discussed above). Pearson’s correlation and Spearman’s rank tests were performed on normally and non-normally distributed variables respectively. Primary dendrite length and proximal branching density showed a significant correlation with fewer than half of the total variables (P>0.05) and so were excluded from PCA. The remaining variables all showed a significant correlation (P<0.05) to at least ¾ of total variables and so were included.

A PCA with extraction of Eigenvalues greater than 1 through an oblique (promax) rotation with Kaiser normalisation was performed on the training sample. A Kayser Myer Olkin measure of sampling adequacy (0.844) indicated a sufficiently large sample size while Bartlett’s test of sphericity (P<0.0001) allowed rejection of the null hypothesis that the correlation matrix was an identity matrix.

PCA produced a 3 component solution that accounted for 77.1% of the variance within the data. The rotated pattern matrix showing the variables contributions to the components is shown in Table 2. The first component comprised soma diameter, primary dendrite cross-sectional area and min and max Feret and accounted for 45.5% of the variance in the data. This component represents the size of the RGC soma and primary dendrite thickness. The second component comprised the number of primary dendrites and PBPF and SBPF areas representing proximal dendritic tree size (accounting for 21.2% of the variance). The third component comprised both PBPF and SBPF CGO and PD range (accounting for 10.4% of the variance) thus representing asymmetry in the proximal dendritic tree. The contribution of the individual variables to the 3 dimensional separation of the RGC population is shown in Figure 5.

Proximal dendritic measurements can define RGC types

RGCs in the training sample (n=101) were grouped using discriminant analysis. RGCs were grouped according to Sun et al. (2002a). Prior probability for each RGC group was calculated based on group percentages of the training sample population to account for frequency of RGC types among a population. Discriminant analysis generated 3 discriminant
functions for the separation of RGCs into groups. A Chi-square statistical test of the

discriminant functions showed that function 3 had no discriminating ability (p>0.05) and so
does not contribute to the separation of RGC groups. The loadings of the individual
variables onto the discriminant functions are shown in Table 3. The first discriminant function
accounted for 72% of between group variance within the data and describes RGC proximal
dendritic tree size and symmetry, soma size and dendrite thickness. It correlated positively
with soma diameter, primary dendrite cross-sectional area, min and max Feret, SBPF area
and number of PDs. The first discriminant function also showed a negative correlation with
PD range. The second discriminant function (which accounted for 22% of the remaining
between group variance) correlated positively with PBPF CGO, describing asymmetry in the
proximal dendritic field, with a contribution from soma and dendrite thickness. The third
discriminant function, accounting for the remaining 6% of between group variance; the
function showed a negative correlation to SBPF CGO and a positive correlation to PBPF
area. The largest determinant of RGC classification is therefore primary dendrite thickness
and soma and proximal dendritic tree size, with a smaller contribution of asymmetry of the
proximal dendritic tree. This is evident in the clear separation of the group centroids (figure
4) where the first discriminant function separates all RGC types in order of size (where
RGC_A>RGC_C>RGC_D>RGC_B).

RGC types discriminated by proximal dendritic morphology

The discriminant functions correctly classified 73.3% (n=74) of RGCs from the training
sample and 63.3% (n=19) from the hold out sample. This was greater than the correct by-
chance classification of 25%. Discriminant scores are plotted against the discriminant
functions in Figure 6 to demonstrate separation of the RGCs into groups. Classification is
predicted based on RGC group centroids which are summarised in Table 4. The predicted
group percentages for each RGC type are summarised in Table 5. RGC groups can usefully
be discriminated by primary and secondary dendrite variables. Misclassification followed a
similar trend with roughly 25% misclassified to the RGC type closest in morphology to the
correct group. All misclassified RGCs had at least 1 variable (average 3 variables) that was greater than 1 standard deviation from the mean of its correct type.

The relationship between population wide variance and between group variance was explored using the component scores generated through PCA as variables to describe the morphology of each RGC. The components alone achieved only a correct classification in 62.6% of the training sample (n=101) and 60% of the hold out sample (n=30). This indicates that population variance in morphology does not adequately describe the difference between groups.

**RGC subgroups cannot be differentiated**

Discriminant analysis was performed as described initially but where RGCs were grouped according to the subgroups described by Sun et al, (2002a). The original hold out sample did not contain two of the subgroups and so the sample size was increased to 40 RGCs following the same random assignment method. Again, prior probability was calculated based on subgroup frequency. Correct classification was achieved in 53.8% (n=49) of RGCs from the training sample and 35% (n=14) from the hold out sample. While greater than the correct by chance classification (8.3%) it does not yield adequate classification indicating that the ability to resolve subgroups is beyond this model.
Discussion

Our data support the concept that RGCs in the rat retina can be classified using dendrite features that are relatively resistant to early degenerative events. It is important to note that the classification is not as precise as that provided by the dendritic tree as a whole (which includes tertiary and higher dendritic structures) however, the model provides a framework to check for labelling bias in the analysis of RGCs in retinal disease. Our data indicate that eccentricity is not a factor that biased RGC classification on the basis of soma size.

We show that RGCs can be discriminated on the basis of soma and proximal dendritic field size. This is in agreement with Sun et al. (2002a) and other classifications based on RGC morphology where larger RGC_A and RGC_C are separated from the smaller RGC_B and RGC_D based on soma and dendritic field size. We also demonstrate dendrite thickness as an effective parameter for classifying RGC types due to its strong relationship with other features of dendritic tree morphology. Primary dendrite thickness has been found to correlate with soma size, dendritic field size, total dendritic length and branching density in rat triceps surae motoneurons (Chen & Wolpaw, 1994) and cat spinal α-and γ-motoneurons (Ulfhake & Cullheim, 1981; Ulfhake & Kellerth, 1981), all parameters used in the classification of RGC types. We also show that asymmetry in the proximal dendritic tree has a small discriminatory effect on RGC types.

The use of DiOlistic labelling resulted in a number of cells being excluded from analysis as the soma and proximal dendrites were obscured by excessive labelling. However, we justify the use of DiOlistic (rather than Biolistic) labelling since this is not contingent on cell health (Honig & Hume, 1986). Studies in the mouse glaucoma model suggest that the level of reporter expression may be affected by neuronal viability (Williams et al., 2013). This is vital given that the classifications purpose is for use in degeneration where Biolistics is affected by the viability of transcriptional pathways necessary for the expression of fluorescent markers. Ballistic labelling techniques are open to the criticism that they bias for larger cell types since the likelihood of a hit increases with cell size. We did not observe this bias in our sample suggesting that the difference in cell soma size is insufficient
to have a large effect on labelling probability. A higher proportion of RGC_A (at 24%) was found in comparisons to the 18% reported by (Sun et al., 2002a); however this was much smaller than the 60% previously reported (Huxlin & Goodchild, 1997). If soma size were the largest determinant of a given cell being labelled one would expect a higher proportion of RGC_A than RGC_B; almost twice as many RGC_B to RGC_A were labelled in this study. In fact retrograde labelling methods, such as those used by (Huxlin & Goodchild, 1997) bias towards the labelling of larger cell types, which further justifies the use of DiOlistics.

The robust discrimination between cell types is important in the study of degeneration, both in terms of reducing pseudo-degenerative effects arising from inter-type differences in dendritic morphology and also in investigating inter-type susceptibility to disease. Type specific degeneration has been noted in the primate (Weber et al., 1998), cat (Shou et al., 2003), mouse (Leung et al., 2011) (Feng et al., 2013) and rat (Thanos, 1988) but not in DBA/2J (Jakobs et al., 2005) or thy1-YFP-H transgenic mice with experimental glaucoma (Kalesnykas et al., 2012). The Sholl plots in Figure 3 demonstrate the differences in branching pattern and density between RGC types and illustrate effectively how disparity in cell types between populations could be confused for atrophy in studies of degeneration.

We anticipate that the chosen parameters will remain stable during degeneration given that significant reduction in branching occurs only in the distal region of the dendritic tree, as illustrated in Figure 1. Measurement of soma diameter is also included based on its greater resistance to degeneration than the dendritic tree. The dendritic tree exhibits the earliest change in RGCs under degeneration while the soma only undergoes substantial change with advanced/chronic glaucoma (Weber et al., 1998). Significant change in RGC soma size in the rat is seen in chronic glaucoma models, however is similar across all retinal regions (Urcola et al., 2006) and so is unlikely to vary between types. The ability of the system to classify cell types may therefore diminish with substantial degeneration, as soma and secondary and primary dendrite degeneration occurs. The inclusion of dendritic stratification depth within the IPL could enhance the correct classification of RGC types, in particular the classification of RGC_D due to their bistratified dendritic tree.
The reproducibility of this model requires testing on a range of degenerated RGC populations, the scope of which was beyond the current study. However, applying the model to a degenerated population of RGCs would not serve to validate the model given that the correct type of an RGC cannot be determined from its post-degenerative morphology while following the degeneration of single RGCs over time is reliant on reporters whose expression is compromised in degeneration.

We would not anticipate complete neuronal classification in view of the large variability in RGC morphology and overlap between groups for any single morphological criterion. Consistent with this, all misclassified RGCs exhibited one or more variable measurement greater than 1SD from the mean of its type. The correct subtype classification of just over a third of RGCs provides encouragement for success if given a larger population. It is also possible that the misclassified atypical cells represent previously unidentified cell types given that the number of RGC types currently defined in the closely related mouse is 22 (Voelgyi et al., 2009). The main role of this classification procedure is therefore not the definitive classification of all RGC types but to provide a degree of confidence regarding RGC proportions in a sample population where traditional methods of classification are vulnerable to bias.

**Figure 1. Example of a degenerated Sholl plot.** Graphical representation of a Sholl plot from healthy and degenerate RGCs as observed in Williams *et al.*, 2010; Weber *et al.*, 1998; Morgan *et al.*, 2006. Under moderate degeneration Sholl plots show high deviation (grey shaded area) from healthy plots distal to the soma, with little deviation proximal to the soma. Primary and secondary dendrites occur within this proximal region and are therefore more likely preserved. Measurements of primary and secondary dendrites may therefore provide robust and stable classification criteria.
Figure 2. Distribution of recorded RGCs. Retinal eccentricity of 114 RGCs shown as distance from the ONH. RGC types show an even spread through retinal quadrants and central/peripheral retina demonstrating minimal regional labelling biases in DiOlistic delivery.
Figure 3. Variation of Sholl plot between RGC types. Mean Sholl plot (n=131) and Sholl plots of RGCs grouped according to type reveals the variation within the pooled population. The plots highlight how analysis of an unclassified population of RGCs could suffer from intrinsic bias through disproportionate numbers of cell types; the leftward shift observed in degeneration is also seen when comparing healthy types. Classification is therefore critical in removing type specific biases. Error bars show SEM.
Figure 4. RGC types. RGC types display a characteristic morphology, represented by z-compressed confocal images and tracings of typical cells of each type (Bistratified RGC_D is depicted as inner and outer IPL stratifications, left and right tracings respectively). Arrows denote axon. Scale bar = 100µm.
Figure 5. Principle component analysis of RGCs. PCA generated 3 components to describe variance in RGC morphology. The component scores of each RGC (n=131) for the 3 components are plotted in X, Y and Z dimensions. When labelled according to type (RGC_A=blue, RGC_B=green, RGC_C=orange, RGC_D=purple), this separation of the data corresponds to the 4 RGC types (A). The variables weightings towards each component are plotted in this rotated space (B). The components represent condensed variables derived from correlated or co-varying variables (those encompassed by broken lines). Soma diameter, PD cross-sectional area and minimum and maximum feret length weight highly on component 1. Primary and secondary branch point field area and PD number weight highly on component 2 while the both the PBPF and SBPF centre of gravity offset and PD asymmetry weight highly on component 3. The overlap in RGC size can be seen in the distribution of types along the 1st and 2nd components (C) however taken together RGC types can be fairly separated based on the soma and proximal dendritic field size where RGC_A>RGC_C>RGC_D>RGC_B. Inclusion of the 3rd component allows for a separation of RGC
types according to asymmetry in the proximal dendritic field as evidenced by clear separation of RGC\textsubscript{B} and RGC\textsubscript{D} from RGC\textsubscript{A} and RGC\textsubscript{C} along the 3\textsuperscript{rd} component \textit{(D and E)}.

\textbf{Figure 6. Discriminant analysis of RGCs.} The discriminant scores of each RGC \textit{(n=131)} are plotted in X, Y dimensions corresponding to the first two discriminant functions. Here variance between groups is maximised so that group centroids (black pentagons) are at maximal distance from each other. RGC classification into a given group is achieved when distance to group centroid is shortest for that given group. The area in which this is true defines the group boundary. When labelled according to type it can be seen that the majority of RGCs are correctly classified to their group by the discriminant functions.
