The appearance of drug-resistant strains of Mycobacterium tuberculosis (Mtb) poses a great challenge to the development of novel treatment programmes to combat tuberculosis. Since innovative nanotechnologies might alleviate the limitations of current therapies, we have designed a new nanoformulation for use as an anti-TB drug delivery system. It consists of incorporating mycobacterial cell wall mycolic acids (MA) as targeting ligands into a drug-encapsulating Poly-DL-lactic-glycolic acid polymer (PLGA), via a double emulsion solvent evaporation technique. Bone marrow-derived mouse macrophages, either uninfected or infected with different mycobacterial strains (Mycobacterium avium, Mycobacterium bovis BCG or Mtb), were exposed to encapsulated isoniazid-PLGA nanoparticles (NPs) using MA as a targeting ligand. The fate of the NPs was monitored by electron microscopy. Our study showed that i) the inclusion of MA in the nanoformulations resulted in their expression on the outer surface and a significant increase in phagocytic uptake of the NPs; ii) nanoparticle-containing phagosomes were rapidly processed into phagolysosomes, whether MA had been included or not; and iii) nanoparticle-containing phagolysosomes did not fuse with non-matured mycobacterium-containing phagosomes, but fusion events with mycobacterium-containing phagolysosomes were clearly observed.

1. Introduction
Tuberculosis (TB) is mainly a burden of the developing world, but has also a great impact globally with an estimated annual 8.6 million incident cases. It also ranks as the second leading cause of death from communicable disease (second to Acquired Immunodeficiency Syndrome (AIDS)) with 1.3 million deaths reported in 2012 [1]. TB-AIDS co-infection has become such a frequent occurrence in third world countries. In comparison to TB alone, TB/AIDS patients have severely reduced survival times, are more challenging to diagnose [2] and may exhibit sometimes fatal immune reconstitution inflammatory syndrome (IRIS) when subjected to anti-retroviral therapy [3]. Standard first line chemotherapy is not effective for individuals that are infected with multi-drug resistant (MDR) Mtb strains and there is practically no cure for extensively-drug resistant (XDR) ones. Failure to complete the lengthy drug regimens allows the pathogens to become resistant especially to the two first line drugs, isoniazid (INH) and rifampicin (RIF). This is increasingly evident in persons who have been previously treated for TB [4]. It is now imperative to discover new chemotherapies against this mycobacterium as well as to enhance the efficacy of existing drugs to combat MDR and XDR forms [5]. In addition, it is important to find new technologies for targeting chemotherapeutic agents and toxic host cell effector molecules through the lipid-rich wax-like mycobacterial cell wall [6].

Innovative nanotechnologies have been designed and tested to meet the challenges posed by the pathogen and poor drug efficacy. Their potential to improve compliance, efficacy and affordability of therapy makes them especially suited for addressing the treatment of TB and AIDS. Nanomedicine (the medical application of nanotechnology) has the potential to improve bioavailability, reduce toxic side effects, reduce drug–drug interactions and overcome drug resistance. Furthermore, nanoformulations can improve drug solubility and facilitate

intracellular drug delivery as well as target drugs to the site of infection. Nano drug delivery systems are generally prepared with natural or synthetic compounds (i.e., polymers and lipids) using various techniques to yield particles ranging in size between 10 and 1000 nm in diameter [7]. Many groups have used poly \( \text{Dylactic-co-glycolic acid (PLGA)} \) as the polymeric encapsulating material because it is non-immunogenic, biodegradable and has the capacity to encapsulate hydrophobic and hydrophilic agents [8]. PLGA was also shown to be selectively taken up into macrophages and dendritic cells [9], the main targets for infection with \( \text{Mtb} \) [10]. In addition, the cytotoxicity of PLGA was evaluated in vitro and in vivo and no significant adverse effects were noted [11].

Nanencapsulation of drugs for delivery provides an opportunity to incorporate targeting strategies to further enhance drug efficiency and limit systemic toxic side-effects to the patient. By functionalizing the surface of the particles with a targeting ligand, higher bioavailability could be generated at the site of infection and therefore the dose and side effects of the drug are minimized [12]. An effective targeting strategy will impact positively on drug delivery to the site of infection, may direct the trafficking of the drugs into organelles in which pathogens are harboured and may improve the release and longevity of the active drug. A comprehensive review of the recent advances in targeting with drug carrier designs for TB was done by Dube and colleagues [13].

The mycobacterial cell wall is composed of many compounds that could serve as targeting ligands. Among these, mycolic acids (MA) are promising candidates because they are the dominant lipids found in the outer cell wall envelope of Mycobacterium species [14]. MA are long 2-alkyl 3-hydroxy fatty acids and in \( \text{Mtb} \), MA consist mainly of alpha-, keto- and methoxy classes, typically 70–90 carbon atoms in length, each containing mixtures of homologs of varying chain lengths and, in some cases different stereochemistry around functional groups in the main (methyl) chain [15]. The various subtypes of MA have been shown to play a major role in the virulence of the pathogen [6,16]. MA from \( \text{Mtb} \) have interesting biological activities, including foam cell formation and immune steering towards Th1 cellular responses [17–19], as well as cholesterol like properties [20,21]. MA was also shown to be immunogenic. When presented by CD1b molecules on dendritic cells, proliferation of human CD4\(^+\), CD8\(^-\) (double negative) T-lymphocytes occurs [22,23]. In addition, anti-MA antibodies are found in human TB-positive patient serum [24]. Mycobacterial MA has never been tested as a ligand for improving nanocapsulated anti-tuberculosis (anti-TB) drug targeting. An attractive hypothesis would be that the MA present on the external surface of the NPs may interact with anti-MA antibodies in the vicinity of the sites of infection to cause a localised immune complex that may enhance uptake of the NPs in the infected and surrounding uninfected macrophages. MA could also target cholesterol present in the plasma membrane of infected or infectent macrophages [25,26] and, more interestingly, in the membrane of phagosomes in which pathogenic mycobacteria are harboured [27], by means of its attraction to cholesterol [20,21,28].

To understand whether or how this happens demands an intricate knowledge of the cellular and molecular mechanisms of survival of the pathogen of interest and more precisely how the pathogen uses or diverts the cellular machinery to its advantage. It is well known that the preferred site of residence of pathogenic mycobacteria in the host macrophage is the immature phagosome [29] which is unable to fuse with lysosomes [30,31]. However, mycobacteria internalized in clumps, a frequent event in the case of \( \text{Mtb} \), are unable to block phagosome maturation [32–35]. In this case, phagosomes mature and fuse with lysosomes to become phagolysosomes. Interestingly, mycobacteria do not die in this cytolytic environment from which they are eventually rescued to reside in phagosomes that no longer fuse with lysosomes [29]. Several more recent studies also indicate that \( \text{Mtb} \), but not \( \text{Mycobacterium bovis} \) BCG or \( \text{Mycobacterium avium} \), may evade phagosomes to survive in the host cell cytosol immediately prior to host cell lysis [36–39].

The subcellular localisation of PLGA particles in cells is a field that has hitherto yielded conflicting results over the past decade. On the one hand, PLGA particles were suggested to be able to escape the endomembrane compartments into the cytosol of a smooth muscle cell line within minutes after phagocytic uptake [12,40]. More groups supported this interpretation for different cell types, including macrophages [41–43]. On the other hand, the PLGA particles were suggested to remain within the phagolysosomal compartment for several days [44–46]. Another issue is the ability for PLGA particles to reach the compartment in which mycobacteria reside. One group suggested this possibility [47], but others could not demonstrate it [10,45].

Previous efforts to demonstrate a potential benefit of MA as a drug-targeting ligand utilized fluorescently labelled MA in a human myelomonocytic cell line by means of confocal laser-scanning fluorescence microscopy (CLSM) [48]. The fluorescently labelled MA in NPs were shown to be actively taken up by the cell lines. In the present work, we assess the use of mycobacterial MA as a ligand for nanocapsulated anti-Mtb drug targeting on the uptake and intracellular fate of the NPs by electron microscopy (EM) methods. It is important to recall that EM is the only technique that can combine sensitive protein detection methods with detailed information on the ultrastructure and interaction of mycobacteria and cellular compartments. A nanofomulation of incorporated MA in a PLGA polymer was achieved via the double emulsion solvent evaporation technique. INH was incorporated as the anti-TB drug model in our PLGA particles due to its known cytotoxicity as a first line drug against actively replicating \( \text{Mtb} \). We chose to infect mouse bone marrow-derived macrophages (BMDM) with either \( \text{Mtb} \), \( \text{M. bovis} \) BCG or \( \text{M. avium} \). Six days later, cells were exposed to the synthesized NPs, with or without the potential targeting ligand MA. We show that MA enhanced the uptake of NPs into mycobacterium-infected macrophages. Newly formed nanoparticle-containing phagosomes were processed into phagolysosomes within hours. Such phagolysosomes were able to fuse with and deliver their contents to mycobacterium-containing phagolysosomes but not to immature phagosomes. We now clearly demonstrate that NPs do co-localise with mycobacteria in the phagolysosomal compartments.

### 2. Materials and methods

#### 2.1. Chemicals and reagents

Dimethyl sulfoxide, ISOsodium (99%), mycobacteria-derived MA, PLGA 50:50 (MW: 45,000–75,000), Polyvinyl alcohol MW: 13,000–23,000 partially hydrolysed (87–89%), Sodium dodecyl sulphate, Triton X-100, Trypan blue, Basic fuchsin, Dulbecco’s modified Eagle’s medium (DMEM), Tyloxapol and Gluteraldehyde grade I (EM grade) were purchased from Sigma-Aldrich Chemical Co., (St Louis, MO, USA). Foetal bovine serum (FBS) was from Biowest (Nuaillé, France), phosphate-buffered saline (PBS) was from Gibco (distributed by Invitrogen, Villebon sur Yvette, France), and osmium tetroxide and Spurr resin were from Electron Microscopy Sciences (distributed by Euromedex, Mundolsheim, France). Middlebrook 7H9, 7H10 agar and Oleic acid–albumin–dextrose–catalase (OADC) were from Difco Inc. (Detroit, MI, USA). Bovine serum albumin conjugated to gold particles (BSA-Au) was purchased from the Utrecht University School of Medicine (Utrecht, The Netherlands).

#### 2.2. Preparation of NPs

The double emulsion solvent evaporation freeze drying technique was used as previously described with modifications [49]. PLGA 50:50 (MW: 45,000–75,000) was dissolved in 6 ml of dichloromethane (DCM) at a concentration of 1.25% weight/volume (w/v). For particles containing MA, isolated MA from \( \text{Mtb} \) (2 mg, 1.7 μmol) was dissolved in 2 ml DCM and added while stirring. For the first water-in-oil (w/o) emulsion, 2 ml of aqueous PBS, pH 7.4, was added to the mixture and homogenized at 5000 rpm for 3 min in a bench-top homogenizer at 4 °C. For NPs containing INH, INH (100 mg, 729 μmol) was dissolved...
in PBS and then added to the mixture. The emulsion formed was subse-
quent transferred to an aqueous stabilizer solution of 2% (w/v) polyvi-
yl alcohol. The second water-in-oil-in-water (w/o/w) emulsion was
formed by homogenization at 8000 rpm for 7 min, then stirred at
500 rpm overnight at atmospheric pressure and room temperature to
evaporate the organic solvent. The PLGA NPs were recovered by cen-
trifugation at 845 and 33,902 rcf respectively for 15 min. The resulting
particles were dried by lyophilization in a Virtis Benchtop freeze dryer.

2.3. Nanoparticle characterisation

NPs collected after lyophilization were subjected to size and size dis-
tribution (polydispersity index) measurements by means of dynamic
light scattering as well as surface potential measurements by means of
laser doppler electrophoresis using a Zetasizer NanoZS instrument
(Malvern Instruments Ltd, UK). NPs were also deposited onto alumi-
um stubs and coated with carbon in a glow-discharge apparatus to
examine their surface morphology by scanning electron microscopy
(SEM).

2.4. Quantification of INH and MA within NPs

Quantification of the INH encapsulated in the NPs was performed via
the direct method. Lyophilized NPs (10.0 mg) were suspended in 10 ml
0.05 M NaOH and kept at room temperature (RT) overnight with con-
tinuous agitation. The samples were then neutralised with 0.1 M HCl
and analyzed via UV spectrometry at 260 nm [50].

Carbolfuchsin dye was used to quantify the amount of MA present in
the NPs [51]. The MA-containing NPs (20.0 mg) were dissolved in chlo-
roform (10 ml) and stirred overnight. Hexane was added to precipitate
the PLGA, and stirred vigorously for an hour. The precipitate was recov-
ered by filtration through a 0.45 μm organic solvent resistant filter ( Pall
Acrodisk) and washed twice to three times with hexane. The hexane ex-
tract was evaporated with nitrogen gas. The MA left in the vial was re-
dissolved in hexane (1 ml) followed by the addition of an equal amount
of carbolfuchsin dye. The absorbance of the hexane layer was mea-
sured at 492 nm in an absorbance plate reader and a standard
curve was compiled.

2.5. Immuno detection of MA on particle surfaces

The presence of MA on the surface was confirmed by Enzyme-linked
immunosorbent assay (ELISA). Preparation of the ELISA plates was done
as previously described with modifications [28,52,53]. Where liposomes
were used in the inhibition of serum anti-MA antibodies in litera
ture (75 μg MA/1 μl of serum), we used MA-NPs (2 μg MA/1 μl of serum).
MA for coating of the ELISA plates was prepared by dissolving the lipid
in hexane (3 μg/50 μl), vortexing for one minute, heating at ~85 °C for
1 min and left to stand at room temperature for 15 min. Hexane
without MA served as coating control. The ELISA plates were coated with the MA
at 50 μl per well using a Hamilton syringe. Plates were stored in a plastic
bag at 4 °C overnight. The coated plates were blocked with 0.5% Casein/
PBS pH 7.4 (400 μl/well) at RT. After 2 h, the blocking buffer was aspirat-
ered and serum (1:20 dilution in 0.5% Casein/PBS, pH7.4) was added to
the plate (50 μl/well). Before the TB positive and negative human sera
were added to the wells, the serum was incubated for 1 h with PLGA
NPs with or without MA (2 mg/ml). Human sera used for analysis of
NPs were from a TB-positive patient serum and a healthy control, both
collected by Anton Stoltz of the Department of Internal Medicine (In-
fectious Diseases), Faculty of Health Sciences, University of Pretoria
and were approved by the University Ethics Committee (159/2011 of 1 Sep-
ember 2011). Samples were centrifuged to remove particulate material
and the supernatant was added to the plates (50 μl/well). After 1 h of in-
cubation, the wells were washed three times with a Well Wash4 ELISA
washer (Labsystems). The wells were then exposed to goat anti-human
Immunoglobulin G (H + L) peroxidase conjugate (50 μl/well) for
30 min at RT. After the incubation the wells were washed three times
with Casein/PBS, then incubated at RT with 50 μl per well of the sub-
strate solution consisting of 10 mg of ODP plus 8 mg of Urea–H₂O₂ in
10 ml of citrate buffer to develop the peroxidase activity. After 30 min,
the plate was read with a SLT 340 ATC photometer at 450 nm with a ref-
erence filter at 690 nm. Background binding of the serum to the plate
was corrected for by subtracting the average binding signal of serum
to MA from that registered for the hexane coated wells. Statistical com-
parisons of ELISA results were performed using the student t-test at a
confidence level of 95%.

2.6. Mycobacteria

Three different mycobacterial strains were used: i) M. avium. The
transparent colony variant TMC 724 (serovar 2) was prepared as earlier
described [32]. Briefly, mycobacteria of a first passage were expanded
after isolation from the liver of C57BL/6 mice infected 6–8 weeks pre-
viously. Mycobacteria used for experiments were always of the first
passage grown on Middlebrook 7H10 agar plates, supplemented with
0.5% Tween 80, 0.2% glycerol and 10% OADC; ii) M. bovis BCG Pasteur
1173P2 was grown in Sauton’s medium containing 0.05% tyloxapol;
iii) Mtb H37Rv was grown in Middlebrook 7H9 supplemented with
0.5% Tween 80, 0.2% glycerol and 10% OADC. For all three strains, ali-
quots of bacterial suspensions were concentrated in Middlebrook 7H9
medium devoid of Tween and stored at −80 °C. When required, frozen
samples were quickly thawed, vortexed and adjusted to the desired titre
in complete cell culture medium. At least 90% of the mycobacteria were
morphologically intact and viable at this stage.

2.7. Cell culturing and phagocytic uptake

Bone marrow cells were isolated from femurs of 6- to 8-week-old
C57BL/6 female mice and seeded onto tissue culture dishes (Falcon,
Becton Dickinson Labware, Meylan, France) of 35 mm in diameter
(4 × 10⁵ cells per dish) or on 24-well tissue culture plates (1 × 10⁵
per well). The culture medium was Dulbecco’s modified Eagle’s medium
(DMEM) with high glucose (1 g/L) and high carbonate (3.7 g/L) concen-
trations supplemented with 10% heat-inactivated foetal bovine serum
(FBS), 10% i-cell conditioned medium (a source of CSF-1), and 2 mM
l-glutamine. At 5 days after seeding, the adherent cells were washed
twice with DMEM and re-fed with complete medium. Medium was
then renewed on day 6. No antibiotics were added. Seven-day-old mac-
rophages were infected for 4 h at 37 °C with either M. avium at a Multi-
plicity of infection (MOI) of 20, M. bovis BCG at a MOI of 5, or Mtb at a
MOI of 2. Infected cells were washed four times of ice-cold PBS to
eliminate non-ingested bacteria, and further incubated in complete
medium devoid of antibiotics.

2.8. Treatment with NPs and chase in NP-free medium

After active replication of mycobacteria for 6 days, infected cells
were exposed to INH-encapsulated PLGA NPs (0.1 mg per ml of medium),
with or without the targeting ligand, MA, for 2–4 h. Cells were
washed gently with three successive changes of DMEM and re-
seeded with fresh medium, with or without MA, for additional 2 days.
Mycobacteria were treated with gentamicin (200 μg/ml) for 2 h. Mycobacteria
were washed twice with ice-cold PBS to eliminate non-ingested bacteria, and
further incubated in complete medium devoid of antibiotics.

2.9. Labelling of lysosomes with BSA-gold

To label lysosomes, M. bovis BCG-infected macrophages were rinsed
with serum-free medium and incubated for 30 min at 37 °C with colloi-
dal gold particles of 10 nm in diameter conjugated with bovine serum

albumin (BSA-Au) diluted in serum-free medium. Cells were washed three times with serum-free medium and further incubated in complete medium devoid of BSA-Au for 2 h at 37 °C. BSA-Au-treated cells were then exposed to NPs as described above. At selected time points during the treatment or the chase period, cells were fixed and processed for EM. Nanoparticle-containing phagosomes were examined for the presence or absence of BSA-Au.

2.10. Processing for conventional EM

Cells were fixed for 1 h at RT with 2.5% glutaraldehyde in 0.1 M Na-cacodylate buffer, pH 7.2, containing 0.1 M sucrose, 5 mM CaCl₂, and 5 mM MgCl₂. After this, they were washed with complete cacodylate buffer, and post-fixed for 1 h at RT with 1% osmium tetroxide in the same buffer, but devoid of sucrose. Cells were then washed with buffer, scraped off the dishes, concentrated in 2% agar in cacodylate buffer and treated for 1 h at RT with 1% uranyl acetate in 30% methanol. Samples were dehydrated in a graded series of ethanol and embedded in Spurr resin. Thin sections (70 nm-thick) were stained with 1% uranyl acetate in distilled water and then with lead citrate.

2.11. Quantification

At the time points indicated, 100 to 200 different cells were examined using the EM to determine the number of NPs per cell profile. Nanoparticle-containing cell profiles were then examined to determine the percentage of NPs enclosed in phagolysosomes. Cells were examined at random and care was taken to avoid serial sections.

3. Results

3.1. Production and characterisation of NPs

The freeze dried particles, recovered after the encapsulation of INH and MA by the double emulsion evaporation technique, were used in all experiments without further purification. The physical characteristics of the NPs used in the present study are summarized in Table 1. During the manufacture both large (800–900 nm) and small (220–250 nm) particles were formed. Because of the bimodal size distribution nature of the sample the two fractions were separated by varying the centrifugal force, with the larger particles sedimenting at relatively low g-forces as compared to smaller particles that needed relatively high g-forces. Yield for the particles with or without the inclusion of MA was similar. Collected large particles represented 32% whereas the small particles represented 10%. The production yield of the encapsulation process was 42% of particles over the initial solid mass of the reactants. The different NPs were next observed under a SEM. Irrespective of size, the SEM images were mostly spherical and their surface was generally smooth and uniform. These data demonstrated that inclusion of MA into PLGA induced a significantly higher phagocytic uptake of NPs by macrophages.

3.2. Inclusion of mycobacterial cell wall MA into PLGA enhances phagocytic uptake of NPs by macrophages

MA are considered to be one of the major virulence factors of pathogenic mycobacteria. Given their location in the outermost layer of the cell wall, and their ability to bind cholesterol, we investigated whether their inclusion into PLGA would affect phagocytic uptake of NPs by macrophages. For this, BMDM were infected with either Mtb, M. avium or M. bovis BCG and left to incubate for 6 days. The cells were then exposed to PLGA or PLGA/MA particles for 2 h, fixed and processed for electron microscopy.

The (+) indicates the standard deviation (n = 3).
such as BSA-gold (BSA-Au) chased to lysosomes prior to uptake of NPs (Fig. 3A, B, C), or simply based on their electron-dense lysosomal contents (Fig. 3D, E, F) (see e.g., de Chastellier et al., 2009[54]). To this aim, uninfected cells or cells infected with \textit{M. bovis} BCG were exposed to BSA-Au chased to lysosomes prior to phagocytic uptake of PLGA or PLGA/MA particles. NP-containing phagosomes were observed under the EM for the presence or absence of the lysosomal marker BSA-Au during uptake of NPs (0\textsuperscript{–}4 h uptake). Three different categories of phagosomes were encountered: i) BSA-Au-negative phagosomes containing a single NP. These phagosomes were often surrounded by many BSA-Au-positive lysosomes (Fig. 3A); ii) BSA-Au-positive phagosomes containing a single NP (Fig. 3B) and, iii) BSA-Au-positive phagosomes containing two or more NPs (Fig. 3C). The first category corresponds to an immature phagosome while the two other categories correspond to phagolysosomes that have acquired lysosomal material following their fusion with lysosomes.

NP-containing phagosomes were then scored for the presence or absence of BSA-Au. For both types of NPs, 90 to 100% of the phagosomes containing 2 or more NPs were processed into BSA-Au positive phagolysosomes within a 1-h exposure. In the case of phagosomes containing only one NP, phagosome processing into phagolysosomes was slower. Forty percent of the PLGA/MA-containing phagosomes vs 25% of those containing PLGA NPs also contained the lysosomal marker after a 1-h exposure. This percentage increased with the exposure time in such a way that by 4 h about 78% of the phagosomes with a single NP were BSA-Au positive, qualifying them as phagolysosomes.

Due to the rapid excretion of BSA-Au from BMDM lysosomes (see, e.g. de Chastellier et al., 2006[27]), it was not possible to use this marker during the chase period. We therefore screened for the presence or absence of the naturally dense lysosomal material which is typical and easy to visualize in BMDM lysosomes and phagolysosomes (see e.g. de Chastellier et al., 2006[27]). Cells either uninfected or infected with \textit{M. avium}, \textit{M. bovis} BCG or \textit{Mtb} were exposed to PLGA or PLGA/MA particles for 2 h. Cells were washed and re-fed with NP-free medium for up to 9 days. At selected time points during the chase period, NP-containing phagosomes were observed and scored for the presence or absence of dense lysosomal material. Qualitative aspects of NP-containing phagosomes that were positive for dense lysosomal material are shown (Fig. 3D, E, F). Throughout the chase period, 90% of the phagosomes containing either one or more NPs of either type displayed dense lysosomal material and could therefore be classified as being phagolysosomes.
panels A and B: Infected BMDM exposed to PLGA or PLGA/MA particles for 2 h were infected with *M. tuberculosis* and were examined for eventual alterations in shape and size. It is important to note that on thin sections observed under the transmission electron microscope, NPs often display an ellipsoid shape rather than the spherical shape as observed by SEM. This is due to unavoidable sectioning constraints and is not a sign of degradation. At the outset of the chase period, the vast majority of NPs had smooth surfaces (Fig. 4A). During the chase period, blebs appeared on a small fraction of both NP populations (Fig. 4B) and towards the late time points much smaller NPs were found in phagolysosomes (Fig. 4C). A quantitative evaluation of the particle size was performed over a 0 to 5-day chase period. No significant size decrease was observed for PLGA particles. In contrast the size of PLGA/MA particles decreased by 25%. This might be due to the slight amphiphilic nature of MA, which could play the role of additional surfactant that facilitates faster degradation of the NP and loss of MA from the NP surface although one cannot exclude that PLGA might also be degraded by lysosomal enzymes and pH. The percentage of NP-positive cell profiles as well as the average amount of NPs per cell profile was also assessed during the same period of chase. For both PLGA and PLGA/MA, the percentage of NP-positive cells (Fig. 4D) as well as the amount of NPs per cell profile (Fig. 4E) started to decline after 2 days of chase. After 5 days of chase, the mean number of NPs per cell profile remained higher in cells exposed to PLGA/MA than in those exposed to PLGA particles (3.6 and 0.7, respectively), and for both cases, macrophages still contained NPs after a 9-day period of chase (data not shown).

3.5. NPs are targeted to mycobacterium-containing phagolysosomes

We then determined whether PLGA or PLGA/MA NPs reached endomembrane compartments already harbouring different strains of mycobacteria. For this, *M. avium* or *M. bovis* BCG-infected cells were incubated with the NPs that were chased for 0 to 9 days. As expected, NPs were not encountered in phagosomes containing a single mycobacterium and devoid of dense lysosomal material, which correspond to non-matured phagosomes. In contrast, both large and small NPs, with or without MA, were found in some phagolysosomes containing either one or several mycobacteria (Fig. 5A, B, C, D). With the large particles, co-localisation of NPs and mycobacteria occurred starting from day 5 of chase and with a higher frequency when MA had been included in the PLGA polymer. Interestingly, the small NPs were delivered to mycobacterium-containing phagolysosomes much sooner, starting from day 1 of chase.

4. Discussion

The aim of the present work was to design a novel nanoformulation with targeting ligands that would improve efficacy of anti-TB drug delivery. Addition of targeting ligands to the surface of nano drug delivery vehicles have been shown to have beneficial properties such as lowering dosages required and reducing toxic side-effects [7]. Targeting ligands that were studied to date include sugars (for instance mannosae), proteins (for example antigens such as peptides), nucleic acid aptamers and antibodies [55–60]. In a fresh approach, we incorporated mycobacterial cell wall MA, a highly hydrophobic molecule, as a targeting ligand into a drug-encapsulating PLGA polymer. MA is an attractive targeting ligand for several reasons. Amongst all targeting candidate ligands considered to date, MA is by far the most robust and stable. This highly hydrophobic molecule could indeed be detected intact in 9000 year old mummified corpses of humans who succumbed to TB [61]. Another important feature of MA is that it is a major virulence factor of pathogenic mycobacteria [19].

Our results showed that the mere inclusion of MA as reagent in the preparation of drug loaded PLGA particles caused them to be exposed on the outer surface of PLGA/MA particles. We also observed a strong

3.4. Degradation/loss of NPs is a slow process

*Mtb* treatments make use of free drugs that may be partially or totally degraded as they progress towards the site of infection. Consequently, higher doses and/or longer treatments have been used to avoid transfer of low doses that may induce drug resistance. Nano-encapsulation of first line drugs such as INH is an interesting alternative for circumventing the negative effects of long treatments and/or high doses provided that the polymers used for drug encapsulation resist degradation during progression towards infected cells and are only progressively degraded to deliver the drugs after their internalisation by target cells.

To test NP alteration/degradation and/or secretion from host cells, infected BMDM exposed to PLGA or PLGA/MA particles for 2 h were washed and re-fed with medium devoid of NPs for a period of 0 to 9 days. At selected time points, cells were fixed and processed for EM. NPs were first examined for eventual alterations in shape and size. It is important to note that on thin sections observed under the transmission electron microscope, NPs often display an ellipsoid shape rather than the spherical shape as observed by SEM. This is due to unavoidable sectioning constraints and is not a sign of degradation. At the outset of the chase period, the vast majority of NPs had smooth surfaces (Fig. 4A). During the chase period, blebs appeared on a small fraction of both NP populations (Fig. 4B) and towards the late time points much smaller NPs were found in phagolysosomes (Fig. 4C). A quantitative evaluation of the particle size was performed over a 0 to 5-day chase period. No significant size decrease was observed for PLGA particles. In contrast the size of PLGA/MA particles decreased by 25%. This might be due to the slight amphiphilic nature of MA, which could play the role of additional surfactant that facilitates faster degradation of the NP and loss of MA from the NP surface although one cannot exclude that PLGA might also be degraded by lysosomal enzymes and pH. The percentage of NP-positive cell profiles as well as the average amount of NPs per cell profile was also assessed during the same period of chase. For both PLGA and PLGA/MA, the percentage of NP-positive cells (Fig. 4D) as well as the amount of NPs per cell profile (Fig. 4E) started to decline after 2 days of chase. After 5 days of chase, the mean number of NPs per cell profile remained higher in cells exposed to PLGA/MA than in those exposed to PLGA particles (3.6 and 0.7, respectively), and for both cases, macrophages still contained NPs after a 9-day period of chase (data not shown).
and significant increase in phagocytic uptake of MA coated NP by mycobacterium-infected macrophages. The facilitation of phagocytic uptake might be best explained by binding of MA-coated NP to cell surface receptors, such as scavenger receptors, involved in phagocytic uptake of Mtb [62].

Our data also suggest that tuberculous mycobacterial derived MA can act as anti-TB drug targeting ligand, according to a mechanism of pathogen mimicry. The cholesterol nature of MA and its ability to bind cholesterol [21] could not only serve as a ligand for cholesterol-rich lipid-raft-like areas on infected cells, or more general cholesterol-rich surfaces associated with granulomas, but may have transformed the NPs to mimic oxidised low density lipoproteins that could be taken up from circulation by macrophages through scavenger receptors. A major consequence of the enhanced phagocytic uptake of NPs coated with MA is that this could in turn lead to a much improved delivery rate and concentration of active drug into the infected cells.

Fig. 3. The preferred residence of PLGA and PLGA/MA particles is a phagolysosome. A, B, C) BMDM were infected with M. bovis BCG. At day 6 p.i., cells were exposed to BSA-Au which was chased to lysosomes prior to phagocytic uptake of large PLGA or PLGA/MA particles. A) 2 hr uptake of PLGA NPs. BSA-Au — positive lysosomes (Ly) are located in the close vicinity of a phagosome containing a single NP and no gold particles; B) 2 hr uptake of PLGA/MA. A BSA-Au-positive Ly is fusing (arrowheads) with a phagosome containing a single NP; C) 2 hr uptake of PLGA/MA. This phagosome contains 2 NPs and BSA-Au (arrow), indicating that it has fused with Ly. D, E, F) BMDM were infected with M. bovis BCG. Six days later cells were exposed to NPs, fixed and processed for EM. D) 4 hr uptake of large PLGA NPs. The phagosome which contains a single NP is fusing with (arrowheads) a Ly filled with dense material (arrow); E) 4 hr uptake of large PLGA/MA. This phagosome which contains several NPs is filled with dense Ly material (arrow); F) 2 hr uptake of small PLGA/MA followed by a 24-hr chase into NP-free medium. This phagosome which contains several NPs is filled with dense Ly material (arrow). Bars in panels A to F), 0.5 μm.
Several studies on NP-driven drug targeting have been aimed at defining the fate of NPs after phagocytic uptake by infected macrophages. Among the different possibilities, localisation in endomembrane compartments, and more especially in phagolysosomes seemed to us the most appropriate. We have, therefore re-investigated this issue with EM approaches. It is important to recall that EM is the only technique that can combine sensitive protein detection methods with detailed information on the ultrastructure of cellular compartments. Contrary to recent information[63], NPs can be easily visualised under the EM provided that the appropriate solvent is used for dehydration steps. We first labelled lysosomes by exposing BMDM to BSA-Au that was chased to lysosomes prior to addition of NPs. At later time points, when BSA-Au had been secreted by macrophages, lysosomes were identified by the presence of electron dense lysosomal material. We concluded that both the MA decorated and non-decorated NPs were localised within phagolysosomes within a few hours after their uptake by macrophages and that they remained in this compartment for at least 9 days. Similarly our small and larger sized non-decorated PLGA NPs resided in the phagolysosomes for up to 9 days in primary murine macrophage cells. Our data definitely put an end to contrasting data presented in the literature for the localisation of unmodified PLGA particles in cells. Panyam et al. reported that differently prepared PLGA particles were able to lysosomes prior to addition of NPs. At later time points, when BSA-Au had been secreted by macrophages, lysosomes were identified by the presence of electron dense lysosomal material. We concluded that both the MA decorated and non-decorated NPs were localised within phagolysosomes within a few hours after their uptake by macrophages and that they remained in this compartment for at least 9 days. Similarly our small and larger sized non-decorated PLGA NPs resided in the phagolysosomes for up to 9 days in primary murine macrophage cells. Fig. 4. Degradation/loss of NPs engulfed by BMDM is a slow process. BMDM infected with M. tuberculosis or M. bovis BCG were exposed to 800 nm-diameter PLGA or PLGA/MA particles for 2 h and then re-fed with particle-free medium for 0 to 5 days. At selected time points, cells were fixed and processed for TEM. A, B, C) Three major types of particles were seen under the TEM, viz. normal-sized NPs with a smooth surface (A), or with small blebs (arrows) at their surface (B), or NPs for which a significant size decrease was observed (C). D, E) Quantitative evaluation of the percentage of NP-containing cell profiles (D), and of the amount of NPs per cell profile at the same time points. The inserts indicate the number of particles per class of NP intensity (E). The values shown are accurate to about +/− 12% based on the evaluation of 60 to 100 cell profiles. Bars in panels A, B, C), 0.5 μm.
escape the phagosomes into the cytosol [12,40], whereas Kalluru and colleagues in 2013, indicated by means of various techniques, that at least 90% of PLGA particles remained in phagolysosomes after in vitro uptake in BMDM cultures [45].

Clear proof of colocalisation of NPs and mycobacteria in the same macrophages has been recently reported in the zebrafish model [63] but, not of colocalisation in the same cellular compartment. At first glance, this may seem logical, because the vast majority of NPs were found to locate to phagolysosomes, while pathogenic mycobacteria reside and replicate in phagosomes that they prevent from maturing and, as a result, from fusing with lysosomes or phagolysosomes (reviewed in, e.g. de Chastellier, 2009 [34,54]). However, mycobacteria prevent phagosome maturation only when they establish and maintain a close apposition with the phagosome membrane, a phenomenon typically observed with single mycobacterial cell occupation of phagosomes. Whenever several mycobacteria are enclosed in the same phagosome — a frequent event in the case of M. bovis BCG or Mtb, such phagosomes mature and fuse with lysosomes (reviewed in, e.g., de Chastellier, 2009 [54]). Phagolysosomes with multiple mycobacterial occupation would then also be able to fuse with NP-containing phagolysosomes. As a consequence one may therefore anticipate co-localisation of NPs and mycobacteria. It is important to confirm this, because depending on experimental conditions, such NP-containing phagolysosomes may contain up to 50% or more of the mycobacterial population phagocytosed by macrophages. Our current study gives the first clear proof of drug loaded NPs becoming enclosed within the same phagosomal compartment as the infecting mycobacteria. For both the large and the small NPs, with or without the MA, incidents of co-localisation were observed, but at a higher frequency when MA had been included in the PLGA polymer. Such phagosomes always contained dense lysosomal material, confirming them to be phagolysosomes. The smaller NPs were found to co-localise quicker than the larger particles did.

One major question that arises is whether the drug-loaded NPs have an effect on M. tuberculosis or BCG growth and/or degradation. In our previous study [48] human macrophage like cell lines were exposed to MA liganded/unliganded, INH loaded particles for up to two days to confirm antibiotic efficacy. At five hours of incubation, the results of drug efficacy were still found to be variable, but after one or two days of exposure the inhibitory effect of INH was clearly confirmed, also when delivered from MA liganded nanoparticles. In the present study, BMDM cells were exposed to MA liganded/unliganded, INH loaded particles for only two hours, after which the cells were washed and maintained in particle free medium before fixation for EM analysis. This prevented us from observing the efficacy of intracellular INH release, more especially as the particles were shown to degrade very slowly over time which could assist in the slow release of the drug. This corroborated the report by Tracy et al. on in vitro studies done with PLGA microspheres [64], reviewed by Fredenberg in 2011 [65]. The active INH content of the NPs could in future be adjusted to an effective concentration that takes into consideration both the slow drug releasing nature of the PLGA particle and the degree of targetting achievable by the MA ligandation. The concentrations of INH in the particles used for the EM observations were approximately 5 μg/ml in the preparation medium, ten times less than a recent in vitro study of an INH analogue that was tested in PLGA particles [47]. As mentioned before, INH-PLGA NPs have shown sustained drug release over several days in vitro and in vivo [66] and allowed a reduction in treatment frequency in mice and guinea pig models [67–69]. Most chemotherapeutic efficacy studies

Fig. 5. Both PLGA and PLGA/MA, either large or small, are transferred to mycobacterium-containing phagolysosomes. BMDM infected with either M. bovis BCG (A, C, D) or M. avium (B) were exposed to PLGA or PLGA/MA for 4 h. At selected time points between 0 and 9 days of chase in NP-free medium, cells were fixed and processed for EM. Thin sections were observed for the presence of NPs within mycobacterium-containing phagosomes. A) exposure to large PLGA NPs, chase for 5 days; B) exposure to large PLGA/MA, chase for 9 days; C) exposure to small PLGA NPs, chase for 6 days; D) exposure to small PLGA/MA, chase for 6 days. In all cases, NPs were found in phagolysosomes containing at least 2 mycobacteria. Arrows point to the phagosome membrane. Bars in panels A, B, C, D), 0.5 μm.
in TB on these types of formulations are conducted in vivo, and will be addressed in future work. The in vitro BMDM approach tested here allows better understanding of why targeted anti-TB nanomedicine may work better in vivo.

We propose that the MA-decorated PLGA-based targeted nano-therapeutic, which arguably could be applied both as an inhaled product or an oral formulation, will improve drug delivery at sites of infection to ensure a high localised release of drug, while maintaining low blood levels; thus with minimal toxic side-effects of the drugs. It was previously reported that MA-laiganded PLGA particles, intradermally injected into rabbits, caused no measurable degree of inflammation, compared to a Freund’s Incomplete Adjuvant control [70]. Combined with a lower dose frequency, this may facilitate the management of the Directly Observed Treatment (DOTs) programme for TB therapy recommended by WHO for global TB control, This is especially relevant for patients with drug resistant TB [71].

With multi- and extensively-drug resistant TB (MDR/XDR-TB) most of the financial resources expended on TB in sub-Saharan Africa [72], the scope provided by the positive indication of MA as targeting ligand for anti-TB nanodrugs could provide timeous hope for a positive solution to a serious current global health threat. These potentially powerful benefits of the targeted nanodrugs could therefore best be trialled in multi-drug resistant TB patients where the issue of toxicity of second line antibiotics treatment is especially prominent.

Acknowledgements

This study was partly funded by the South African Department of Science and Technology, South African National Research Foundation and South African Council for Scientific and Industrial Research. This work was also supported in France by core grants from the Institut National de la Santé et de la Recherche Médicale (INSERM) and the Centre National de la Recherche Scientifique (CNRS) to the Centre d’Immunologie de Marseille-Luminy (CIML) and by grant ANR-09-MIEN-009-03 from the Agence Nationale de la Recherche (French National Research Agency) to GJC.
